Physical, biological, and chemical proxies preserved within coral skeletons provide details of changing environmental conditions that can add to our larger-scale understanding of spatial and temporal changes in the reef environment over time. Smaller versions of the drilling systems designed to recover reef cores have been used to extract samples from living corals (Figure 1a). X-radiographs of corals reveal annual density bands that can be used as “calendars” by simply counting back from the live coral surface. When banding can be used to pinpoint specific time horizons within a coral, biochemical markers that are referenced to them can be used to hindcast a variety of oceanographic parameters. For example,  $^{18}\text{O}/^{16}\text{O}$  and Sr/Ca ratios reflect changes in temperature and salinity (Greer et al., 2009). Carbon isotopes can be used to assess the relative importance of photosynthesis at various times and at different places on the reef (Omata et al., 2005). Fluorescent bands in the same corals can be used to identify sudden increases in terrestrial sediment and nutrient input (Isdale, 1984). Even sediment can be trapped within a coral skeleton, providing direct evidence about the type and intensity of terrestrial input associated with natural or anthropogenically induced events in the past (Barnard et al., 1974; Cortes and Risk, 1985). Risk et al. (1987) have proposed that annual cycles of algal micro-boring may provide insight into the evolution of photosynthesis in corals throughout the Phanerozoic. Collectively, these windows into past oceanographic

conditions provide us with important information about short-term changes that cannot be discerned in the averaged record of larger-scale reef accretion.

### How reefs build

In addition to these insights into the history of specific reefs, important lessons have also been learned about the processes by which modern reefs build and how this compares to reefs formed throughout deep time. Ecological patterns respond to active processes that are, in turn, controlled by the edifice upon which they rest. Thus, corals owe their zonation to the depth gradients created as the end product of thousands of years of accretion as well as oceanographic process that are likewise affected by the large-scale morphology of the structural reef.

Until recently, it was assumed that reefs owe their rigidity and wave resistance to largely in-place and interlocking organisms. Calcification and coral growth were thought to exert the primary control on how fast a particular reef built. However, coring studies in the 1970s and 1980s provided a number of important, if counterintuitive, revelations. First, preserved coral skeletons only make up about a third of the material inside most Holocene reefs – and not all of these are preserved in growth position (Hubbard et al., 1998). The remainder of the reef interior consists of sediment, rubble, and open voids. Quantitative budgets that compare the “accretionary potential” of a reef (based on present-day abundance of corals and their rates of carbonate production) to what is actually preserved within that reef show that large quantities of carbonate are missing (e.g., Stearn and Scoffin, 1977; Land, 1979; Hubbard et al., 1990).

These findings encouraged a reassessment of the fundamental principles upon which our models of reef development are based. While corals and other skeletonizing organisms provide the building blocks for the reef, calcification is not the only – or even the primary – process that contributes to reef building. Over half of the carbonate produced by large skeletal organisms is reduced to sediment by organisms that graze on or bore into reef organisms. This weakens the initial structure and facilitates further physical and chemical breakdown, as well as the toppling and transport of coral colonies. The result is a structure that is as much detritus as it is in-place “reef-builders.” Were it not for the ubiquitous processes of cementation (probably mediated by bacteria – see Section) and encrustation (primarily by calcareous algae and other epibionts like foraminifera and bryozoans – see Section), this “garbage pile” would not be the rigid and wave-resistant structure that we call a coral reef.

Thus, paradigms that embrace the dominance of calcification in reef building have been replaced by alternative models in which calcification, bioerosion, cementation, and encrustation play roughly equal roles. A recent compilation of available reef-accretion data in Caribbean reefs has further decoupled initial calcification from net reef accretion (Hubbard, 2008). Despite the rapid decline in

**Reef Drilling, Table 1** Accretion rates within 5-m paleo-depth intervals. Note that no strong depth- or species-related pattern emerges from the data (Based on data from Hubbard 2008)

Mean accretion rate ( $\pm$  S.D.)

| Depth (m)      | N   | <i>A. palmata</i> | Massive         | Total           |
|----------------|-----|-------------------|-----------------|-----------------|
| 0–4.9          | 47  | $3.96 \pm 3.45$   | $2.53 \pm 1.65$ | $3.58 \pm 3.12$ |
| 5–9.9          | 40  | $4.33 \pm 3.00$   | $2.78 \pm 3.23$ | $3.79 \pm 3.13$ |
| 10–14.9        | 31  | $2.43 \pm 1.90$   | $3.19 \pm 2.45$ | $2.82 \pm 2.20$ |
| 15–19.9        | 7   | $2.09 \pm 0.17$   | $3.74 \pm 3.58$ | $3.27 \pm 3.04$ |
| 20–24.9        | 3   | 5.52 na           | $1.38 \pm 0.74$ | $2.76 \pm 2.45$ |
| <b>Overall</b> | 128 | $4.65 \pm 4.38$   | $3.17 \pm 3.28$ | $4.10 \pm 4.06$ |

light intensity, calcification and coral growth with increasing water depth, reef accretion appears to not follow the strong depth-related pattern that has been long assumed (Table 1). Reefs in shallow water and dominated by fast-growing branching corals built at rates that were statistically indistinguishable from reefs in deeper water and dominated by massive colonies. Although reefs appear to have accreted more rapidly, cores from the Great Barrier Reefs show a similar pattern (Davies et al., 1985; Hopley et al., 2007). If this is the result of decreasing rates of bioerosion with depth and the logical tendency for sediment to move downslope, then reef accretion might be thought of more as a sedimentological process than a biological one.

### Is what you see what you get?

Comparisons between modern and ancient reefs face numerous challenges, depending on the age of the reef and the way it is examined. In outcrops, a reasonably complete, three-dimensional picture is available. However, adequate temporal control can be difficult in reefs older than the Quaternary. We can assign a general age to an older reef, but it is difficult to accurately date individual corals and, therefore, to assign rates to what we see in the rock record.

As we go further back in time, problems of changing taxa are introduced as the march of evolution becomes increasingly significant. Within a Holocene reef, organisms are the same as those on the surface. Quaternary reefs were built by organisms that are either still in existence or can be easily traced to extant species. But, as we go further back in time, this gets increasingly difficult. For example, 340 million years ago reefs were built by stromatoporoids that probably responded differently than corals to depth gradients and variations in physical processes.

### The taphonomic filter

Even in a well-exposed outcrop, myriad processes have been at work that create differences between what actually existed on the sea floor in the past and what is ultimately preserved in a fossil reef. Collectively referred to as taphonomy, these issues are related to everything that happened to an organism from the time it died to when it was

(or was not) fossilized. Obviously, soft-bodied organisms are preserved only in unusual circumstances. Fragile skeletons (e.g., platy corals) will break down more easily than branching ones, which are in turn less preservable than massive colonies. Rare taxa are less likely preserved than more abundant ones. Finally, postmortem disintegration and transport can move smaller fragments considerable distances from their initial environment, especially where slopes are high or storms are frequent. If we add later diagenetic processes to the mix, fidelity to the original community structure is even further compromised. These problems are greatly moderated in reefs, which contain so many robust skeletal taxa. Nevertheless, diversity may still be reduced by up to 90% as reef organisms pass through the “taphonomic filter.”

### Time averaging

Anyone who has spent much time on a reef appreciates the spatial and temporal variability that exists within even a small area. If we scale this up to the millennia over which reefs build, a seemingly infinite combination of species might occupy a particular spot on the reef over its lifetime. The result is a fossil record in which a sampling of corals over even a small area or a short length of core can represent huge time spans. Because of this “time averaging,” it can be difficult to separate changes in species related to environmental variability from those that simply reflect the decadal changes that normally occur on any reef. Even if we use what appear to be identical methods, the results may not be comparable. For example, a quadrat on a reef (Figure 9a) provides a detailed accounting of species abundance and diversity at one place and at one instance in time. In contrast, that same quadrat placed on a rock face (Figure 9b) will contain an amalgam of the corals that were preserved over perhaps a millennium or longer. Similarly, a transect survey over a live reef (e.g., the irregular line in Figure 8a) records spatial variability, and it is easy to determine which corals are live or dead at that instant. Even if we were able to somehow identify a similar time-equivalent surface within an outcrop (Figure 9b), it is difficult to determine which corals beneath that imaginary line were alive or dead at the same time. If we further limit ourselves to the vertical sampling provided by a core through the reef, these problems increase.

### Why is reef zonation preserved at all?

Given all the ways that the original community structure can be modified before burial and the myriad issues of selective preservation over long intervals of time, one might wonder how reef zonation is ever preserved. While in-place corals may not make up the majority of the reef as was previously thought, those colonies that are left behind still provide important information about the environment in which they lived and died. Also most larger colonies that are toppled do not move significant distances from their original location and will probably end up in or near their original environment, even if they are not “in place,”

**Reef Drilling, Figure 9** Comparison of quadrats (*squares*) and transects (*irregular lines*) on the modern reef surface and along fossil-reef outcrops. The quadrat on Davies Reef in the Great Barrier Reef (a) tallies what exists in that square meter at a particular time. In contrast, that same quadrat placed on the Holocene reef wall in the Dominican Republic (b) will contain corals that existed over some time span, probably on the order of 1,000–4,000 years. Similarly, the transect across the reef in (a) provides an accurate accounting of organisms along a depth gradient, and it is easy to differentiate live and dead corals to obtain an accurate measure of coral cover. Even along the timeline created by storm burial in the DR fossil reef (b), it is difficult to tell which corals were alive or dead at an instant in time (Photos by permission of the author).

they are still *in situ*. Sediment and rubble trickles down inside the reef where it is deposited, or it is transported to some other place – either on the reef, or far away if storms or steep slopes come into play. Nevertheless, enough of the community structure is preserved to allow most of the large-scale inferences that we commonly make from outcrops and cores.

### Potential coring artifacts

In addition to issues of selective loss and preservation, a number of potential problems that are specific to the coring process must also be kept in mind. The rotating drill bit can fragment more fragile samples and, combined with water flow through the core barrel, it can push smaller samples out of the way. Sediment recovery is virtually impossible. Slower rotation speeds, maintenance of constant pressure on the drill bit (i.e., not letting it jump up and down, especially in rubble-dominated intervals), and minimizing water flow can greatly reduce these problems, but only rarely can they be totally eliminated.

Slowly augering or pounding thin-walled core barrels by hand (without water flow) can reduce or even eliminate the loss of smaller samples, rubble, and sediment (Dardeau et al., 2000). However, this process is tedious and is able to penetrate only 2–3 m under ideal conditions in unconsolidated, finely branching corals. Pneumatic coring has been used to drive a core into the reef by

percussion rather than by rotation. Recovery is excellent and selective losses are minimized. However, this method is limited to shallow water where air-pressure losses are minimal and safe handling of large pneumatic equipment is possible. It has been proposed that using larger core barrels (>15 cm) might improve recovery. However, this has not been systematically tested, and anecdotal observations argue against it, except when compared to very small core barrels ( $\leq 5$  cm) where high loss rates are known to occur.

### Accurate core logging

Use of a traditional tripod can make it hard to reliably determine the exact vertical position of a recovered sample, even within a single 1.5-m core interval. Reefs are typically very porous, and cavities can be open or filled with sediment and rubble derived from biological breakdown of the reef. During coring, the lifting cable is typically left slack to make sure that drilling progress is unimpeded. When the unsupported drill string encounters an open void, it free-falls until it either reaches the bottom of the hole or the slack in the lifting cable is taken up. In this scenario, the bottom of the void can be easily determined by measuring the length of the drill string in the hole at that point. However, unless the operators have been exceedingly vigilant, the top of the void will be based on the collective recollection of the stunned crew regarding where the rig was just before it plummeted. When a core

barrel is recovered, it is often less than half-full, owing to the porous nature of the substrate. Where the core interval ends in a continuous and solid substrate, the position of that single piece can be accurately determined. However detailed measurements for small samples and interspersed voids are rare, and placing the numerous small pieces in an accurate vertical context is often difficult. This can affect calculations of reef-accretion rates.

Resolving this issue requires a drilling system in which the drill string is positively controlled as coring proceeds. In one such system, an adjustable tripod is incorporated into a rigid frame that provides stability (Figure 10).

Rather than being loosely hung on a wire, the drill motor travels along two rails, and is both raised and lowered by a chain drive that precisely maintains the position of the drill string throughout the coring process (Figure 10d). The crank handle that operates the chain drive maintains constant pressure on the bit throughout drilling. Vibrations caused by the drill bit interacting with the substrate are passed up the drill string, along the chain drive and into the drive handle. These vibrations, plus the rate of penetration in response to a reasonably steady downward pressure, provide tactile feedback from even small changes in the nature of the substrate. An open void is instantly

**Reef Drilling, Figure 10** Photographs of the SCARID drilling system. (a) Drilling frame deployed along the shallow reef crest in Buck Island Underwater National Monument, US Virgin Islands. The operator (*left*) uses hydraulic power to rotate the drill string, control water flow, and raise and lower the messenger that is used to recover the inner core barrel. (b) Drill frame deployed in 13 m of water on Lang Bank, St. Croix, US Virgin Islands. The drill string is to the right of the coring tower. Controls are located on the backside near the diver. Water and power come through hoses from the surface. (c) Drill on the bottom beneath its support catamaran. The drill and the water pump are powered by a 17-hp diesel on the platform. Easy launch and recovery are facilitated by the open section in the center of the catamaran. The system has been used on modest vessels of opportunity, and requires only an open deck on the order of 4 m  $\times$  4 m. (d) Divers operating the SCARID drilling system. The diver on the right is maintaining drilling pressure on the core barrel using a handle attached to the stainless steel drive chain. Note the metric scale on the left side of the drill frame. This provides a convenient and accurate reference for the vertical position of the drill string in the hole. The operator uses predetermined hand signals to indicate drilling character to the back-up diver who records this information along with the position at which each change occurs (Photos by permission of the author).

registered through the drive handle, and low gearing makes it easy to immediately stop any free fall. Sandy intervals are rapidly traversed, but with easily discerned resistance. In rubble intervals, the feel of the bit bouncing against the irregular and mobile surface is unmistakable. Solid intervals require increased pressure that is proportional to the resistance of the substrate being cored (primarily reflecting coral density).

The result is an ability to sense and locate even small changes in the reef interior. Each time the drilling character changes, the position of the drill motor is referenced to a metric scale mounted on the drilling frame (Figure 10d). Using these notes and the lengths of the recovered samples, a log can be created that accurately locates each sample and adequately interprets the unrecovered intervals in between (Figure 3c). Early testing involved trying to match the number of solid samples in a core barrel (and their lengths) to the intervals recorded in the drilling notes. These predictions were usually accurate to within 5% of what was actually found when the inner barrel was emptied.

The main disadvantage of this system and other sophisticated coring systems is the greater logistical complexity associated with them. Even small jack-up rigs (e.g., Figure 5c) need to be towed to the site and require sufficient water depth over the reef to float them into place. Larger traditional systems (e.g., Figure 5a) are limited to dry land or to water depths shallow enough to allow easy access and little potential for wave overtopping. Drilling frames like the one used in the submersible coring apparatus for remote insular drilling (*SCARID*) system can be used in all environments (Figure 10), but can still be more cumbersome and require better trained scientist/divers to deploy and operate them. However, the increased predictability (nearly all cores taken with larger systems penetrate through the entire Holocene section and little time is lost getting stuck in the hole) can result in significant time offsets. Once in place, the additional weight of larger drills translates into greater stability and a significantly increased level of accuracy with respect to sample location and core logging. Considering the funds required to mount a field operation and analyze the recovered samples, the increased cost of deploying a moderately larger system is probably less of an issue than assembling a crew that is adequately trained to take advantage of its positive attributes.

### The "Two-Inch Outcrop"

Even with the largest and most reliable drilling system, cores provide a limited picture of the reef interior. The myriad issues discussed above notwithstanding, a single core is the equivalent of a 5–10-cm wide outcrop that provides a single, vertical characterization of the reef interior. However, multiple cores that are accurately located along a well-constrained transect can provide a good three-dimensional picture as long as adequate vertical control of sample positions and sufficient radiometric dates are possible (Figure 6). The central question is always,

"How many cores are enough?" Using uniquely exposed Holocene reefs in the western Dominican Republic, detailed vertical transects were measured to create "virtual cores." Each "virtual core" was located both vertically and horizontally using differential Global Positioning System (GPS) measurements and laser surveys. Radiocarbon dating temporally constrained the patterns of reef development. Changes in paleo-water depth were computed using each sample's vertical position, its age, and the most-accepted Caribbean sea-level curve (the original Lighty et al., 1982) curve adjusted by using accepted isotopic corrections (e.g., Hubbard et al., 2000; Toscano and Macintyre, 2003; Hubbard et al., 2005). Approximately five evenly spaced "virtual cores" provided a good representation of the large-scale facies patterns that were identified within the full exposure of the 450-m long outcrop. Furthermore, changing depositional patterns seen in the "virtual cores" allowed a general characterization of transgression versus regression across the entire outcrop.

What was consistently missing from the core record, even when more "virtual cores" were added, was an accurate accounting of the full range of species present in the outcrop. Over 25 coral species and 50 mollusc species were identified in the outcrop, but only a handful of coral taxa and virtually no molluscs were sampled by any combination of "virtual cores." Nevertheless, the temporal and spatial changes in major species were still adequate to accurately characterize larger-scale paleoenvironments (i.e., zonation) in the outcrop. Overall reef morphology, and the relationship between facies changes and the rate of sea-level rise were likewise reasonably characterized. Finally, small-scale fabrics within individual samples (e.g., bioerosion, cementation, and encrustation) and their relationship to larger-scale patterns within the reef structure were reasonably constrained. In short, while a detailed characterization of coral-community structure may have been lacking, the larger picture of zonation and shifts of major corals in response to physical-oceanographic processes and sea level still emerged. Thus, despite all the pitfalls of fickle preservation and time averaging, the important relationships that are of interest to geologists were still discernible.

### Summary

The interiors of modern reefs are rarely exposed, leaving few options for collecting information on past reef morphology, internal structure, and history. Well-documented issues with preferential preservation make it obvious that the reef we find preserved is different than the reef that actually existed in the distant past. Issues of recovery and precise positioning of samples add to these problems. Nevertheless, coring remains as our most valuable tool for gaining access to the interiors of modern coral reefs around the world. Despite the known problems, cores have provided a realistic characterization of the primary reef-builders and the general temporal framework over which they have contributed to the rigid and

wave-resistant structures that support today's coral-reef community. Comparisons with continuous exposures indicate that as few as three to five cores can provide a reasonable picture of fossil zonation as well as the pattern of reef building in response to changes in physical oceanography and the rate of sea-level rise and fall. Proxy data from individual corals within a core can provide important information on short-term variability in past ocean conditions. Thus, we can use observations and measurements on modern reefs to better understand the complex relationship between process and product in the past. Applying all these to our cores, we have been able to reconstruct patterns of reef accretion as rising sea level flooded major shelf areas around the world, and have come to understand how the reefs that followed responded to changing physiochemical processes and sea-level rise when "we were doing nothing." The models developed using this information have helped us to tie reef organisms to the structures that they presently occupy. If we remain mindful of the problems associated with interpreting fossil assemblages, we should be able to apply the lessons of reefs operating before major human influence to questions about future changes and suggest sound management strategies that take into account both natural change and the effect of processes that operate over time intervals longer than the attention span of a typical politician, the funding cycle of an individual research project, the life of a scientist, or even the disciplines of biology and geology.

## Acknowledgments

The greatest and most obvious debt is to the researchers who have wrestled with the practical and intellectual problems associated with sampling the interiors of Holocene reefs. Starting with researchers from the Smithsonian Institution and growing into a community of researchers as diverse as the reefs they study, a suite of drilling strategies have evolved that balance simplicity and depth of recovery; the list is too long for adequate individual acknowledgment of the individuals that have made our way easier. Studies by the author that contributed to the information provided in this chapter were funded by the National Science Foundation (St. Croix cores), the Sea Grant and Undersea Research Programs of the National Oceanic, and Atmospheric Administration (fabrication of the SCARID drilling system; cores in Salt River, St. Croix; Puerto Rico and the Florida Keys), the US National Park Service (cores in Buck Island Underwater National Monument), the National Institute for Global Environmental Change (Puerto Rico cores), and the Petroleum Research Fund of the American Chemical Society (Dominican Republic studies).

## Synonyms

Coral-dominated reef flat; Rubble-dominated reef flat

## Definition

Reef flats are the most recent expression of coral reef (see Chapter [Coral Reef, Definition](#)) growth at sea level. There are two forms of reef flats: (1) coral-dominated

and (2) rubble-dominated. In each case, they represent the growth of reefs in the ambient energy conditions as the growing reef approaches the sea-level environment.

### Example of reef flats

One Tree Reef ( $23^{\circ}30'S$ ,  $152^{\circ}06'E$ ) in the Capricorn–Bunker Group in the southern Great Barrier Reef (see Chapter *Great Barrier Reef: Origin, Evolution, and Modern Development*) (Figure 1b) is an example of both forms of reef flats. It is subjected to prevailing trade winds, predominantly from the southeast (Figure 1c), resulting in the formation of reef flat features common to reefs throughout the world. It currently represents one of the largest modern databases in the Great Barrier Reef (Davies, 1983). It is this reef that is used as an example of the development of both coral- and rubble-dominated reef flats.

### Coral-dominated reef flats

The southern reef flat of One Tree Reef is dominated by live coral growth (Figure 1a-i). It is composed of six distinct morphobiological zones; algal flat, rubble band, fused coral windrows, unfused coral windrows, coral patches, and sand flat. Wide algal flats, reef flat windrows, and prograding sand bodies collectively are common sea-level growth signatures on high-energy reefs (Davies et al., 1976; Jell and Flood, 1978; Davies and Marshall, 1979). This zonation is commonly found on high-energy reefs globally.

### Components of the coral-dominated reef flat

#### Algal flat

The algal flat (see Chapter *Algal Rims*) is the most windward zone. It is comprised of epilithic layers of calcareous

**Reef Flats, Figure 1** (a) Aerial photograph of One Tree Reef (i) the southern coral-dominated reef flat (ii) the eastern rubble-dominated reef flat; (b) location of One Tree Reef; (c) wind-rose showing predominant southeasterly winds.

algae and mats of filamentous turf algae (see Chapter *Algae, Turf*) with an endofauna comprised mainly of benthic foraminifera (see Chapter *Foraminifera*). The surface slopes towards the reef front (see Chapter *Forereef/Reef Front*) in a series of laterally discontinuous but distinct algal terracettes.

### Rubble band

Leeward of the algal flat is a thin rubble band (see Chapter *Boulder Zone/Ramparts*) consisting of coral rubble and algae which accumulates on the inner edge of the algal flat. It is widest at the southeastern end, narrowing westward. The coral rubble is largely composed of dead and fragmented plate, branching and massive growth forms.

### Coral windrows

Leeward of the rubble band is the coral windrow zone, occupying much of the upper surface of the southern reef flat (Figure 2). Windrows are elongated structures of coral framework, separated by narrow sandy channels up to 10 m in width. Windrows typically have a solid pavement surface of coral and coralline algae (see Chapter *Algae, Coralline*), where growth has reached the mean low-tide level. The framework of the windrows is composed of robust branching and massive coral growth forms and is consolidated by smaller coral growth forms and coralline algae.

1. Fused coral windrows: Adjacent to the rubble zone, the channels between the windrows are filled with rubble, sediment, and live coral growth such that adjacent windrows fuse together, creating the fused windrow zone.
2. Unfused coral windrows: Leeward of the fused windrow zone are unfused windrows, extending toward the sand flat. This is easily the most discernible zone, comprising the main coral flat.

Reef Flats, Figure 2 Coral-dominated reef flat: coral windrow.

### Coral composition of the coral windrows

Five dominant scleractinian (see Chapter *Scleractinia, Evolution and Taxonomy*) coral growth forms comprise the coral-dominated reef flat at One Tree Reef; branching, massive, encrusting, laminar, and free-living. The distribution of these forms changes both transversally along the length of the windrows from windward to leeward and longshore across the reef flat from southeastern windrows to southwestern windrows.

Longshore variations include the following: (1) massive and encrusting corals dominating the southeastern windrows, while branching and encrusting forms dominate the southwestern windrows; (2) massive and branching corals display an inverse relationship whereby the percentage cover of branching corals increases from the southeastern windrows to the southwestern windrows, while massive corals decrease towards the southwestern windrows; (3) branching coral cover is greatest in the leeward section of the southeastern windrows and the windward section of the southwestern windrows; (4) branching *Acropora* species (see Chapter *Acropora*) count increases by a factor of +3 from the southeastern windrows to the southwestern windrows.

The windrows themselves experience transverse variations in the distribution of the dominant coral growth forms cover. Using the southeastern windrows as a specific example, the windward section of the windrows is dominated primarily by massive corals and secondarily by robust low-branching forms. The leeward section of the windrows is dominated primarily by branching corals and secondarily by massive coral forms.

### Coral patches

The coral patches zone lies leeward of the coral windrows and consists of shallow patches of coral and algae that form discontinuous extensions of the windrows onto and across the sand flat. Coral patches range in size from 2 m to less than 1 m in diameter.

### Sand flat

The sand flat occurs leeward of the coral patches zone, sloping into the lagoon (see Chapter *Lagoons*). It is comprised of medium to coarse coral sand derived from all windward environments (see Chapter *Reef Flats*), coralline algae, foraminifera, molluscs (see Chapter *Molluscs*), bryozoans (see Chapter *Bryozoa*), and sponges (Davies, 1977; Davies and Kinsey, 1977) (see Chapter *Reefal Sediments*).

### Formation of the coral-dominated reef flat

Reefs are subjected to prevailing energy conditions and, in the case of One Tree Reef, predominantly from the southeast (Figure 1c). Therefore, the area most affected by this energy is the southeastern corner of the reef, with energy diminishing transversally toward the lagoon, as well as longshore down the length of the southern coral-dominated flat.

This southeastern corner is also the highest measured point on the coral-dominated reef flat, sloping down both transversally toward the lagoon as well as longshore down the length of the reef flat. Together, the height of the reef substrate and the energy regime compose the main physical and environmental parameters influencing the development of the coral-dominated reef flat. Combining the two, the southeastern corner becomes the shallowest, highest energy point on the reef, with both height and energy dissipating in transverse and longshore directions. The consequence is that higher energy propagates further across the reef at the southeastern corner.

It is reasonably well established that corals and other benthic organisms distribute themselves on the reef flat in response to the ambient environmental parameters (see Chapter *Corals: Environmental Controls on Growth*), including the dominant physical processes to which they are exposed (Done, 1982; Sebens and Done, 1992; Merks et al., 2003; Kaandorp et al., 2005; Kruszynski et al., 2007). While morphologic and biologic variability of reefs involves a plexus of interactions between chemical, biological, and physical processes, wave energy is recognized in many studies as one of the most important controls of coral reef growth and subsequent development at sea level (Roberts, 1974; Done, 1982, 1983; Dollar, 1982; Storlazzi et al., 2005; Kench and Brander, 2006). The southern coral-dominated reef flat of One Tree Reef expresses the effects of these parameters in both transverse and longshore directions, with a number of possible relationships: (1) high-energy and a high-reef surface creates an area dominated primarily by massive and encrusting corals with some robust, low branching on the most windward areas; (2) lower or less energy and a lower reef surface creates an area dominated primarily by branching corals in the leeward section of the most exposed windrows with some massive forms; and (3) the lowest energy and surface creates an area of high diversity (of *Acropora* species) in the windward areas.

### Stages of development

Drill cores reveal that the coral-dominated reef flat is composed of an initial stage of massive coral growth in water depths of approximately 10 m, followed by mixed massive and branching biofacies, with branching corals dominating as the reef approaches sea level (immediately below the current windrow zone) (Marshall and Davies, 1982; Davies and Hopley, 1983). Criteria used for identifying the in situ nature of drill cores include (1) algal crusts atop coral pieces and down the side of solid coral pieces (identical relations are seen on the coral flat today), (2) continuity of long coral pieces in the core, (3) the disposition of adjacent fauna and flora, (4) geopetal cavities, (5) the disposition of crypto fauna beneath or within cavities, and (6) the direction of growth of cyanobacterial finger-like growths within cavities in or on corals. No material was selected for dating if it had been reboored or from the core-catcher.

The development of the coral-dominated reef flat at sea level on One Tree Reef occurs in three stages: formation of aligned windrows and development of the sand flat, formation of the windward fusion zone and the formation of patches, and smothering of the lagoonal micro atolls (see Chapter *Microatoll*) by sand.

Coral windrows are comprised of framework constructors and framework fillers, and are the direct result of the interactions between the two to create a consolidated matrix. Both use the available living space, with one constructing the basic framework while the other consolidating this framework matrix by growing in the secondary environments created by the constructors. The living space created by the primary framework corals provides stability and support by direct contact for such infill species. The strength and physical complexity of this matrix of corals is cemented by coralline algal infill, with additional consolidation occurring with the incorporation of sediment within the coral framework.

Framework constructors are primarily branching and massive corals. Framework fillers are frequently fragile branching forms and include all growth forms, with branching, massive, and encrusting forms dominating. Some coral species may be both framework constructors and fillers depending on their position on the reef flat. For example, *Favites* is a massive framework constructor in the windward section of the windrows, while it is a filler in the leeward section of the same windrows. As the coral framework is established and approaches sea level, and therefore is increasingly affected by the prevailing energy, the corals begin to develop aligned windrows parallel to the dominant flow direction. The windrows in turn diversify the physical conditions in which they grow in relation to gradients in water flow velocity creating biological zonation of the corals (Stoddart 1969; Geister, 1977; Dollar, 1982; Done, 1983; Massel and Done 1993; Rogers, 1993; Storlazzi et al., 2005; Kruszynski et al., 2007).

Simultaneous to the formation of coral windrows is the development of the sand flat. Sand sourced from the coral windrows, produced mostly through bioerosion (see Chapter *Bioerosion*) and physical erosion, is transported leeward by the prevailing energy. This leeward prograding of the sand flat into the lagoon facilitates the lateral leeward expansion of the reef flat. As the sand flat grows, it provides a substrate of suitable depth on which corals can colonize, allowing coral growth to continue in a leeward direction. The rate of this prograding is predicted to decrease as the sand flat moves further away from the dominant sediment source (Davies, 1983).

After the establishment of the coral windrow matrix and sand flat, the process of windrow fusion occurs. The fused zone forms in the windward section of the windrows (most prominently in the southeastern windrows) when the windrow structure has grown to the mean low-tide level and formed a hard surface on the top surface of the structure of predominantly coral and calcareous coralline algae, thereby limiting further vertical growth without

a change in sea level. As a result, the corals grow laterally along the sides of the windrows, often perpendicular to the dominant flow direction, closing in the channel between windrows, resulting in “fusion” of adjacent windrows, obliterating the windrow structure along its length from windward to leeward. After fusion, the hard coral and algal surface is exposed at low tide resulting in its breakdown to rubble. As this process moves leeward, so too does the calcareous algae of the algal flat.

While the coral windrows are fusing in the windward section, the coral patches zone extends the windrows leeward across the sand flat. The initial stage of patch development occurs when storm-transported coral fragments (largely branching species) are transported leeward of the windrow onto the sand flat. These fragments either die or regenerate, becoming a monospecific colony. Small colonies of framework constructors (and few fillers) grow on the dead coral fragments either through further fragment transportation or planulae. As branching corals are often the first to increase their bottom coverage in such nonspace-limited stands and their growth rates are significantly higher than that of planulae-dependent massive corals (Sebens and Done, 1992), branching corals dominate these colonies. These colonies grow over the sand as low patches, touching the sand only in point contact. The patches are eventually consolidated when filler corals, such as *Goniopora* and *Favites*, are added to the framework matrix. These patches then expand through both vertical and horizontal growth until adjacent coral patches fuse together and to the main windrow structure, thereby extending the coral windrows leeward across the sand flat.

Smothering of the lagoonal micro atolls by the leeward extension of the sand flat occurs when lagoonal sands are transported leeward into the lagoon, gradually covering the lagoonal micro atolls. Corals are unable to survive such smothering, and as a result, the lagoonal micro atolls die and are colonized by algae.

### Rubble-dominated reef flats

The eastern reef flat at One Tree Reef (Figure 1a-ii) is a rubble-dominated reef flat, nearly 4.5 km long and up to 0.5 km wide, containing an estimated 14 million tons of rubble (see Chapter *Shingle Ridges*). Drilling has shown a maximum depth of 8 m of rubble material (Davies and Marshall, 1979; Davies and Hopley 1983). It is highest along the lagoonal edge and lowest at the junction with the algal flat. The difference in height between the two averages 40 cm. The boundary with the lagoon is either straight or indented with spurs and gutters. Supratidal islands occur on the intertidal rim in the south and in the north. The islands are comprised of successive rubble storm ridges. The upper surface of the rubble flat is strewn with rubble spurs, all of which indicate derivation from the east and southeast. New rubble spurs are habitually comprised of stick coral rubble above larger massive and plate corals, the whole exhibiting a decrease in grain size. The long axis of most clasts of stick rubble

is at right angles to the direction of movement, suggesting turbulent flow (Gourlay, 1988; Nott, 2003). The material forming the rubble surface commonly exhibits imbrication of plate and massive corals and the alignment of stick coral fragments. The rubble flat shows a clear zonation: massive and plate rubble weighing between 10 and 20 kg dominate the outer flat adjacent to the algal flat (Figure 3); plate and massive rubble weighing between 5 and 10 kg and minor branching forms dominate the mid-flat; and stick rubble and some plate rubble dominate the inner rubble flat adjacent to the lagoon. Often, the stick rubble forms linear mounds on the very edge of the lagoon.

### Formation of the rubble-dominated reef flat

The rubble on the eastern reef flat at One Tree is clearly derived, with no live coral growth occurring currently on the flat (see Chapter *Corals: Biology and Skeletal Deposition*). Imbrication, aligned stick rubble on spurs, storm ridges on islands, and the zonation of the rubble-dominated reef flat itself indicate that the material is derived from the windward reef front below mean low water. Analysis of coral species from both reef front (from mean low water down to depths of 15 m) and reef flat rubble confirms that the same species are present in both environments; indeed, coral rubble identical to that on the flat lies in the grooves between the spurs. It is concluded therefore that live coral is broken on the reef front, accumulates in situ, and is picked up and transported up on to the rubble flat. However, the evidence on the rubble flat itself indicates that transport of material may occur as two separate but related processes: (1) the initial dump of a mixture of material on the outer flat; and (2) the physical separation and sorting of that material on the rubble flat itself. These processes are clearly physical, a statement of which lies in the record of energy impinging on the reef. At One Tree Reef, a summary of this record is shown in Table 1. Energy is a function of wind (velocity and direction) and sea state (wave height, wavelength, and period) and can

Reef Flats, Figure 3 Rubble-dominated reef flat: outer rubble flat.

**Reef Flats, Table 1** Winds, sea state, and physical energy in the system in deep and shallow water. It should be noted that the energy in the system increases by 1.5 orders from low to high energy

| Energy class | Beaufort scale                | Sea state | Wave height (m) | Wind velocity (km/h) | Wave Period (s) | Wave length (m)    | Deep water wave energy (N m) | Shallow water wave energy (N m) |

|              |              |                                                                             | Unsorted dumping of rubble on reef flat. Dumping of rubble into the lagoon |

be calculated quantitatively (Table 1). Wind strength and sea state are strongly related. Using these parameters and calculating energy within the system, four energy states can be defined in the surrounding ocean (Table 2) and summarized as follows:

- Low energy – calm airs to light breezes – total energy of 277–550 N m
- Intermediate energy – fresh to strong breezes – total energy of 1,100–3,600 N m (a three times increase in energy levels over stage 1)
- High energy – near gale to storm – total energy of 3,500–24,300 N m (a 3–10 times increase in energy levels over stage 2)
- Extreme energy – violent storm – total energy in excess of 30,000 N m (a total of 2 times minimum increase in energy levels)

Note that in moving from stage 1 to stage 3 (historically a common annual phenomenon), energy in the system increases by 1.5 orders of magnitude. The historical record of wind and sea state therefore defines the length and frequency of the energy windows which have impinged on

One Tree Reef and reefs like it. When the deep water wave energy approaches a reef edge, a shoaling occurs in approximately 30 m of water (see Chapter *Reef Front Wave Energy*). The energy of the wave moving forward is approximately half of the energy of the deep water wave, the rest of which dissipates against the fore-reef (see Chapter *Wave Shoaling and Refraction, Waves and Wave-Driven Currents* and *Wave Set-Up*). How the forward moving energy is used is then a function of whether it is totally expended on the reef front or whether it is expended across the reef in total; this is dependent on the tides (see Chapter *Tidal Effects on Coral Reefs*). The tides in the Great Barrier Reef region are semi-diurnal and their height varies depending on springs/neaps and solstice/equinoctial time frames with a maximum tidal range at One Tree Reef of 0–3.5 m. In any assessment of energy within the system, therefore, it is important to note that reef flats are periodically covered by nearly 3.5 m of water, while at other times the upper reef fronts and reef flats are exposed. In the context of distribution of energy, therefore, low tides are periods when energy is concentrated almost entirely on the reef front, while high tide periods define

energy distributed across the whole reef system (not equally). In terms of the processes recognized qualitatively as occurring in producing the rubble flat, i.e., breakage, storage, transport and dumping on the outer rubble flat, and sorting on the flat, coupling the energy levels to windows of opportunity (high and low tides) defines when the major processes occur (Table 2).

The frequency of the energy levels reported in Table 1 and therefore the processes described in Table 2 can be gauged from a historical database of wind and tide data. At One Tree Reef, this shows relatively low energy conditions persisting for 270–352 days a year for the past 48 years, with 1960 and 1988 representing intermediate and high energy spikes in this generally low-energy record. However, intermediate- and high-energy events occur every year to some degree, and in nearly all cases, that energy is directed at the reefs from the east to south-east quadrants. In addition, these blow particularly strongly during the January–June period and especially during the equinox and solstice spring tides. The processes and products that comprise the rubble flats therefore occur largely in these periods but mainly in the March–April period.

## Conclusions

Reef flats represent the most recent growth at sea level of modern coral reefs. They are recognized globally as two forms: (1) coral-dominated; and (2) rubble-dominated. Coral-dominated reef flats reflect the interaction between the biotic communities and the energy characteristics of the environment, creating distinct zonations. The coral flat is divided into fused windrows, unfused windrows, and patches. Coral growth forms vary transversally across and longshore the coral flat. Both variations reflect a decrease in reef height and wave energy.

Rubble reef flats are composed of materials derived from the reef front. Here, live coral is broken, accumulates in situ, and is picked up and transported up on to the rubble flat. Transport occurs as two separate but related processes: (1) the initial dump of a mixture of material on the outer flat and (2) the physical separation and sorting of that material on the rubble flat itself. The intensity and frequency of these processes are a function of wind strength, sea state, and tidal condition. Breakage, storage, transport, and dumping on the outer rubble flat and sorting on the flat itself occur at specific energy levels and therefore at specific times and tidal states. Low-energy conditions at One Tree Reef occur throughout most of the year, and in these periods, sand entrainment and transport to the lagoon and sorting of finger rubble on the rubble flat are predominant processes. Intermediate-energy conditions commonly occur during the March and June solstice and equinox cycles when the major processes/products operating are wave destruction/accumulation of branched corals on front, transportation of branched forms to form rubble flat spurs, separation of massive and plate corals on the rubble flat, and imbrication of large clasts.

High-energy conditions predominate in the same time frame, during which time major wave destruction of massive and plate corals and the accumulation of chaotic rubble occurs on the on front.

## Synonyms

Forereef; Reef Slope; Seaward Slope

## Definition

The reef front is the downward-sloping reef section, seaward of the reef crest that normally ends in a sediment apron. Waves undergo transformations over the sloping reef front that redistribute and dissipate their energy.

## Introduction

From the reef crest to depths of 20–25 m, [Figure 1a](#), (fore reef of [Stoddart, 1969](#); [Milliman, 1973](#)) intense sunlight, strong water motion, and nutrients support coral and coral-line algal growth in well-known forereef zones and construct an extensive reef framework. Spurs and grooves with vertical relief of ~2–20 m frequently occur in this reef front zone ([Roberts et al., 1975](#)). Forereef sediments are mainly biogenic sands or coarser particles in pockets, channels, and thin veneers ([Longman, 1981](#)). Seaward and deeper than the forereef (20–25 m), [Figure 1b](#), the lower or deep forereef slope has less sunlight, weaker flows, limited growth of reef-building organisms, and fewer reef framework organisms that include coral heads, gorgonians, and algae ([Stoddart, 1969](#)). Fine sediments in this section consist mainly of coral debris and particles of calcareous algae from shallower areas as well as reef rubble and blocks ([Longman, 1981](#)). The lower slope of the reef front is highly variable between reefs and within each reef, but generally tends to increase in steepness from fringing to barrier reefs and atolls ([Gourlay, 1996](#)). Wave–bottom interactions are affected by the steepness and morphological configuration of the seafloor in both the forereef and deep reef front slope.

Wave–reef interactions start at the lower slope and continue to the breaking point near to and generally seaward of the reef crest. Wave changes across the reef front depend on incident wave period and height and start at water depths  $\leq 50$  m (wave periods  $\geq 8$  s) for most energetic waves. These transformations drive a cross-reef current identified by Munk and Sargent ([1948](#)). Seminal work by Gerritsen ([1981](#)) applied the wave radiation stress concept to wave interactions with coral reefs and established a basic analytical approach in this field. Subsequent oceanographers unraveled other details of wave processes on coral reefs that are summarized by Monismith ([2007](#)). Waves transiting the reef front affect coral and fish zones (e.g., [Bradbury and Young, 1981](#); [Friedlander et al., 2003](#)), productivity, removal of sediments and metabolic wastes, replenishment of nutrients and distribution of food particles ([Patterson et al., 1991](#); [Hearn et al., 2001](#)), transport of sediments (e.g., [Orme, 1973](#); [Davies, 1983](#)), photosynthesis, and calcification of corals ([Dennison and Barnes, 1988](#); [Finelli et al., 2006](#)). During storms, waves cause coral mortality and morphological changes of reefs ([Harmelin-Vivien, 1994](#)). Since Darwin's *Structure and distribution of coral reefs* in 1842, it has been recognized that waves impose major forces on coral reefs systems.

## Wave transformations over the reef front

Because wave speed decreases toward the reef crest due to decreasing water depth, advancing waves change their deepwater direction until they become nearly parallel to the reef crest. This direction change, refraction, allows deepwater wave energy to reach most reefs along a given coast. However, refraction causes shadow or low wave energy zones, as in the leeward of islands

**Reef Front Wave Energy, Figure 1** Two idealized reef fronts with both shallow and deep basin profiles: (a) less steep forereef slopes are generally associated with fringing and mid-shelf barrier reefs and (b) steep forereef profiles are typical of shelf-edge reefs and atolls.

(Roberts, 1974). Spurs and grooves align with incident wave direction across the reef front in response to wave refraction (Munk and Sargent, 1948; Roberts, 1974). Wave energy propagates into the lagoons of some reefs by refraction (Lugo-Fernández et al., 1994). Refraction focuses waves along a reef resulting in wave height increases. A decrease in wave height occurs when the waves are defocused or spread. These wave height changes reflect energy redistribution, not dissipation. Waves propagating toward the crest experience a decrease in wave group speed because of decreasing water depth, and wave height increases to keep the energy density constant. This process, called shoaling, increases the wave height across the reef front without energy dissipation. When energy dissipation is small (e.g., reefs with smoother bottoms), wave shoaling and refraction dominate wave height change across the reef front up to the breaking point (Lugo-Fernández et al., 1994; Hardy and Young, 1996). In this case, the reef front wave height is estimated as

$$H = K_S K_r H_0 \quad (1)$$

where  $H_0$  is the incident wave height,  $K_s$  is the shoaling coefficient, and  $K_r$  is the refraction coefficient.

A more realistic description of wave energy across the reef front is the one-dimensional steady energy conservation equation with dissipation

$$\frac{\partial(Ec_g)}{\partial x} = -(\varepsilon_f + \varepsilon_b) \quad (2)$$

where  $E$  is the wave energy density (proportional to wave height squared),  $c_g$  is the wave group speed,  $x$  is the cross-reef distance, and  $\varepsilon_f$  represents the energy dissipation rate per unit area for bottom friction, and  $\varepsilon_b$  is a similar quantity for wave breaking. For a review of wave modeling, see Cavaleri et al. (2007). Equation 2 states that wave breaking and bottom friction dominate wave energy dissipation over coral reefs but excludes nonlinear effects and dissipation by deformable or permeable bottoms. Massel and Gourlay (2000) incorporated shoaling and refraction in Equation 2.

Because of the presence of large frame-building corals, the reef front exhibits considerable bottom roughness ranging from ~0.2 to 2 m. Bottom roughness decreases as depth increases (Nunes and Pawlak, 2008). Large bottom roughness results in higher drag or bottom frictional coefficients (e.g., Lugo-Fernández et al., 1998a) as confirmed by estimated drag/friction coefficients from Pacific and Caribbean reefs in Table 1. These coefficients are considerably larger than coefficients for sandy bottoms. The important result of higher frictional coefficients is that bottom friction is high and comparable to wave breaking dissipation and cannot be neglected when modeling (analytical or numerical) waves and currents over the reef front.

The final and most dramatic wave transformation over the reef front, visually and in terms of change to the wave form, is wave breaking. Yet, in physical terms, wave breaking is the least understood of wave transformations. While wave breaking is qualitatively well known, researchers resort to semi-theoretical approximations to incorporate wave breaking in models. Usually, waves break near the reef crest, where their height equals  $H_{\max} = h_b \gamma$  ( $h_b$  is the breaking depth and  $\gamma$  is the breaking index). In sloping reefs  $\gamma = 0.7$ – $1.0$  and  $\gamma = 0.55$  at the reef flat; functionally  $\gamma = 0.55 + 0.88 \exp(-0.012 \cot \beta)$  where  $\beta$  is the reef front slope and  $\exp$  is the exponential function (Nelson, 1994). The reef front slope also controls wave reflection. A steeper slope reflects more energy. In most instances, wave reflection appears to be small because the extreme bottom roughness appears to cause diffuse reflection. In the case of breaking waves, large amounts of energy are lost to turbulence and the wave spectrum flattens in the gravity region, but harmonics and infragravity waves may be excited by associated nonlinear processes (McGehee, 1994; Hardy and Young, 1996). Table 2, which updates Table 1 in Roberts et al. (1992), shows that wave energy changes from 72% to 99% mainly through a combination of dissipation and redistribution. In some reefs, frictional dissipation across the front reef exceeds wave breaking (Lugo-Fernández et al., 1998b; Lowe et al., 2005). Because energy dissipation (e.g.,  $\varepsilon_f$  and  $\varepsilon_b$ ) depends on water depth, this dissipation

is modulated by tide, ~13% in microtidal areas (Lugo-Fernández et al., 1998b,c), but higher in macrotidal settings. Two consequences of high wave energy dissipation across the reef front are: (1) reefs function as very efficient wave breakers which protect back-reef shorelines and (2) the reef front is the high wave energy zone not the reef crest which is the high turbulence zone.

### Selected effects of reef front wave energy changes

Most reef front organisms have evolved to withstand everyday wave forces, but during hurricanes wave forces are large enough to severely impact the reef (Massel and Done, 1993; Madin, 2005). Because reefs function as natural breakwaters, during hurricanes and tsunamis they offer some level of protection to coastal areas behind them (Young and Hardy, 1993; Kunkel et al., 2006) but can suffer extreme damage through removal of large blocks of up to 2,000 t deposited on the reef flats (Noormets et al., 2004). Before breaking, waves lower the sea level until just before the breaking point and beyond this point sea level rises to maintain a pressure gradient that drives water into the lagoon (Lugo-Fernández et al., 2004; Gourlay and Colleter, 2005). Finally, because of the high permeability of the reef, waves transiting the reef front drive sub-reef flows that aid both, cementation and porosity development (dissolution) that makes reefs potential reservoirs for petroleum or freshwater (Carter et al., 1989; Haberstroh and Sansone, 1999).

### Summary

In summary, waves transiting the sloping reef front experience decreasing water depths and increasingly rough bottom (high bottom friction/drag coefficients) that cause refraction, shoaling, and energy dissipation (bottom friction and wave breaking). Net wave energy reductions of 72–99% have been estimated from measured wave heights over many reefs that maintain a wave height gradient across the reef front. The resulting reef front wave

field provides energy that drives or supports biological and chemical processes of the reef ecosystem, geological and morphological processes over and in the reef, and a wave-driven flow that connects the reef front to the backreef lagoon. Efficient dissipation of wave energy by coral reefs provides some measure of protection against large hurricane waves and tsunamis to backreef lagoons and shores.

## Synonyms

Larval migration; Larval transport; Natal dispersal; Reef connectivity; Reef population connectivity; Reef population network

## Definition

*Reef interconnectivity*. The flux of larvae between reef locations, creating a network of interconnected reefs – could also refer to the flux of water mass (i.e., oceanographic connectivity), transporting sediments, particulate or dissolved organic or inorganic matter, trace metals and/or pollutants from reef to reef (sensu Paris and Cherubin, 2008).

*Reef population connectivity*. The exchange of individuals among subpopulations during any stage of their life history (sensu Paris et al., 2007) – described as the “exchange of individuals among geographically separated subpopulations that comprise a metapopulation” (sensu Cowen et al., 2007). Further, “realized connectivity” (sensu Pineda et al., 2007) requires that the individual that migrates from a source population survives within the receiving population until it reproduces (or replaces itself).

*Larval dispersal*. The spread of larvae from the spawning site to a settlement site.

*Natal dispersal*. In the broader sense of the term, dispersal is the process of moving away from the birthplace (sensu Clobert et al., 2001). For *coral reefs* and reef-related species that have a sessile or benthic adult phase, dispersal is only possible during the pelagic larval phase.

## Introduction

*Coral reefs* are naturally fragmented at all spatial scales, from the patch reef to archipelago scales. Yet, patchy habitat can be connected in many ways: by the flow

transporting material or by migration of organisms, transporting genes from the parent populations. The movement of individuals between geographically separated populations represents the dynamic interactions defined as *reef population connectivity*. This terminology comes from metapopulation theory, which states that spatially structured populations with distinct units separated by space or barriers are connected by dispersal (Levin, 1969). For those species that are mobile and migrate to spawn, populations can be kept demographically open on relatively large spatial scales by adult movement. In coral reef ecosystems where most species are benthic or sessile, the interactions between breeding populations are mostly taking place through *natal dispersal* during the pelagic larval phase (Sugden and Pennisi, 2006), which represents a unique opportunity to disperse by the currents. The spatial scale of coral reef population connectivity is thus largely determined by the dispersal of larvae, and the success of their dispersal plays a critical role in the persistence of local populations, recolonization of disturbed area, and the range limits of species distributions (Levin, 2006).

## Larval dispersal in coral reef ecosystems

The life cycle of many organisms inhabiting *coral reefs* is complex, consisting of a planktonic larval phase, followed by settlement as a benthic or sessile juvenile and adult. Although the larval phase is a short portion of the life cycle of these organisms, it is critical in assuring relatively rapid dissemination of individuals in the currents. Larvae not only have radically different physiology than their benthic forms but also have very diverse morphologies, pelagic durations (from a few hours in some soft corals to weeks and months in fish and lobsters) and swimming and feeding traits (e.g., some planulae are lecithotrophic and survive on maternal reserves; planktotrophic larvae feed on selected plankton, Llopiz and Cowen, 2009). At the end of the pelagic phase, the larva becomes competent, settles, and metamorphoses into a juvenile, supplying the benthic populations. The fate of larvae is critical in sustaining populations and defining their structure. Indeed, demographic *reef interconnectivity* depends on the relative number of larvae that (1) die of predation or of getting lost (e.g., *coral reefs* occupy a tiny fraction of the ocean's bottom, Donner, 2009), (2) are self-recruiting in the parental population, (3) migrate into distant populations, or (4) colonize new suitable habitat (Gaines and Roughgarden, 1985).

The potential of large losses during the pelagic phase are compensated by high fecundity in coral reef invertebrates and fishes (Bonhomme et Planes, 2000). Thus, balancing the benefit of *larval dispersal* (e.g., reducing reef predation and competition for food, inbreeding depression, risks of extinction, and increasing the persistence of the metapopulation), against potential detriments (e.g., increasing the risks of predation, of settling far from

parent populations, reducing local *adaptations* and selective power, and of settling in suboptimal conditions and reducing post-settlement success) is still open to debate.

### Scales of connectivity

Reef interconnectivity can occur over a continuum of time and space scales ranging from ecological to evolutionary time scales. Low dispersal rates are sufficient to shift the metapopulation distribution spatial pattern over time by a turnover of local populations going extinct and becoming reestablished elsewhere (Levins, 1969). These long-term processes of historical exchange events and species persistence result in evolutionary connectivity (Hanski, 1989). On the other hand, ecologically significant connectivity usually implies that a substantial number of individuals are exchanged each generation in order to sustain linked populations. Therefore, the scales of dispersal relevant to relatively short-term temporal processes are reduced to areas of strong larval exchange and can be approximated to the mode of a dispersal kernel (i.e., probability of successful dispersal distance). Alternatively, from the evolutionary point of view, a small number of exchanged individuals is enough to maintain genetic homogeneity between discrete populations. Therefore, larval exchange relevant to evolution occurs typically at larger spatial (i.e., the tail of the dispersal kernel) and on longer temporal scales. Because of the differences between temporal scales necessary for studies of connectivity, it is critical to formulate the questions and related hypotheses before setting up empirical measurements and/or modeling study. The high levels of percent self-recruitment reported recently have drawn attention to how small the scale of dispersal can be (Jones et al., 1999, 2005; Swearer et al., 1999).

### Description of larval dispersal and reef interconnectivity

Larval transport results from the physical processes of advection and turbulent diffusion and the biological process of larval behavior. However, larval dispersion encompasses all the processes that regulate the dissemination of larvae, including spawning strategies of the parental population (i.e., reproductive mode, time, place), larval transport, survival, and settlement back to selected habitat of the coral reef ecosystem (Pineda et al., 2007). When the settlement process is not included, the terminology of “potential dispersion” is used. When the settling larvae participate to the next generation, the terms of “reproductive dispersion” or “efficient dispersion” are used.

Natal dispersal is measured by the “dispersal kernel”  $K(x,y)$ , the function that describes the probability of a larva to disperse at different distances, or the probability density function (pdf) of the number of settlers versus distance from the adult source (Nathan, 2006). The dispersal kernel is thus a continuous function that represents the

spatial distribution of larval dispersal and is typically represented in two dimensions (Siegel et al., 2003). Because the probability of mortality during larval dispersal is not null, the integral of the distribution in space is always less than 1 ( $0 \leq K \leq 1$ ). The modal distance has demographic relevance, defining population spatial patterns and persistence, while the tail represents Long Distance Dispersal (LDD) with evolutionary implications such as genetic variability and species range expansion (Paris et al., 2007). In empirical estimates, the dispersal kernel may represent a single, or at best a few spawning events from a single location (Figure 1). But to have a probabilistic power, the dispersal kernel should be calculated for a series of spawning times over multiple spawning seasons. So far, only numerical modeling can achieve this level of temporal resolution (Botsford et al., 2009).

Dispersal kernels vary with time and space, driven by spawning location and timing. Indeed, local *hydrodynamics* and larval transport are influenced over a wide range of scales by climatology, the geomorphology of the coastline, the reef topography, and fragmentation (Paris et al., 2002; Munday et al., 2009). Thus, dispersal kernels should differ among locations for species with extended reproductive season (e.g., year-round, lunar cyclic spawning in damselfish). Alternatively, they may be stable with low variance for mass spawners that disseminate their gametes over a very narrow window in time (Baums et al., 2006; Sadovy-Mitcheson et al., 2008). Because larval dispersal includes larval traits and behavior, the shape of the dispersal kernel certainly varies among species (Steneck et al., 2009) from being asymmetrical in cases of high local retention, to bimodal for areas of divergent currents or for species that have a plastic larval competency and relatively long maximum competencies (Shanks, 2009; Butler et al., in review Limn. Oceanogr.). Finally, the magnitude of the dispersal kernel varies as a function of larval mortality, its mode as a function of the advection, and its variance as a function of current variability and diffusion (Paris et al., 2007; Botsford et al., 2009).

Dispersal kernels from multiple spawning locations form the “connectivity matrix.” Each node  $i$  on the x-axis and node  $j$  on the y-axis of the square matrix represents a spawning and settlement location, respectively, while each cell  $M(i,j)$  represents the probability that a larva from a natal reef  $i$  migrates to the settlement reef  $j$  during its pelagic larval duration. Values on the matrix diagonal, when  $i = j$ , represent self-recruitment. Estimating reef interconnectivity will help determine the size of the subpopulations forming a metapopulation. Alternatively, if there is an a priori knowledge of the size of each subpopulation (e.g., based on population genetics), each node  $i$  represents the center of mass of a subpopulation located in a coral reef area  $S_i$ . Probabilities of larval linkages between the subpopulations will help map the metapopulation in which they belong. Metapopulations are thus separated by dispersal barriers.

Reef Interconnectivity/Larval Dispersal, Figure 1 Relationship between dispersal and connectivity.

### Influence of hydrodynamic and biological process

In idealized coastal models described by Siegel et al. (2003), the dispersal kernel only accounts for advection by stationary mean currents and turbulent diffusion, determined by the temporal scales of current fluctuations. While diffusion tends to increase local retention over multiple generations, advection increases the spread of the species. The relative importance of the two processes can be defined by the Peclet number ( $P_e$ ).

Recent studies indicate that despite their small size, coral reef fish larvae are not passive (Leis, 2007 for review). They have a diversity of traits and considerable behavioral capabilities that can lead to successful completion of the early pelagic life phase (Paris et al., 2007). In particular, vertical migration during ontogeny increases retention near natal reefs and decreases dispersion losses, likely enhancing survival (Paris and Cowen, 2004). Larvae can come back to their native reefs or can be exchanged among breeding subpopulations. However, the dynamics of these interactions at both the individual and population levels are not fully understood (deYoung et al., 2004). For those larvae that do not return home, the extent to which larval behavior influences their arrival pattern among adjacent and distant reefs (or larval connectivity network) is not known. More importantly, interactions of the small-scale larval movements with transport

processes due to larger-scale currents need to be quantified with regard to the spatial patterns of recruitment. Since actively moving larvae may be diluted and to some extent dispersed by currents, an in situ study of them is very difficult. Larval behavior is associated with the perceptual range of each individual, representing its informational window onto the environment. For coral reef fish larvae in particular, a suite of sensory systems operating at different scales can play an important role in orientation: acoustic (Simpson et al., 2005) and olfactory (Atema et al., 2002) signals in the shorter range, and possibly visual and magnetic signals (Kingsford et al., 2002) for longer-range navigation. Understanding the orientation behavior of larvae is a prerequisite to understanding, measuring, and predicting demographic (ecological) connectivity and may also be relevant to genetic (evolutionary) connectivity (Paris et al., 2009). Understanding how larvae orientate and the sensory cues they use for orientation constitutes one of the largest gaps in our knowledge of larval behavior.

### Reef interconnectivity and habitat

Population connectivity not only depends on life history but also on the seascape defined by both the local currents and habitat configuration. The interactions between physical and biological factors and their role in shaping

populations have been previously discussed in landscape ecology (Levins, 1969), but this discussion is a relatively recent development for marine ecosystems (Barber et al., 2002; Baums et al., 2006; Cowen et al., 2006). The spatial arrangements and connectivities of marine populations are poorly understood, yet they are assumed to enhance resilience to disturbance and be of critical importance for population persistence (Kinlan et al., 2005; Hasting and Botsford, 2006). Baums et al. (2006) demonstrated that patterns of connectivity are indeed linked to the fragmentation of the coral reef habitat. Connectedness (i.e., number of connected subpopulations) and connectivity networks are changed with extended larval competency period only when distances between habitat patches are significant. This implies that the response from reef populations to *climate change* through the growth rate and survival of the early life history stages is a nonlinear process and may be counterintuitive. Indeed, dispersal kernels are not necessarily shrinking with increased temperature (Paris et al., 2008; Munday et al., 2009).

Maintaining the reef system as pristine as possible is important since it affects the production of larvae and their settlement survival, and subsequently, their recruitment into the adult population (i.e., “realized connectivity” sensu Pineda et al., 2007) and resilience in response to disturbances. Reef damage also impacts reef interconnectivity through the loss of habitat patches that may serve as stepping stone linkages for the population network. Reefs depend on pristine areas for larval production, which is necessary for long-term persistence. If pristine areas are not maintained, eventually the entire reef will likely be lost.

*Coral reef conservation* would benefit from greater understanding of the degree of connectivity between *coral reefs*, or between land and reefs, that may exist through the movement of water masses (Paris and Cherubin, 2008). Land use, such as clearing of native vegetation and replacement with intensive agriculture, has increased pollution transport to the coastal ocean to a level many times the natural rate (McKergow et al., 2005). Degraded water quality of streams has yielded degradation of receiving bodies, such as lagoons and coastal waters, where most *coral reefs* reside. Sediments and nutrients, in excess, are almost universally recognized as having inhibitory or negative effects on reef communities.

### Estimating reef interconnectivity

Larval dispersal is described by the number of larvae  $N$  dispersed as a function of the distance  $y$  from the birth place. Another way to represent dispersion is to describe a dispersal kernel representing the probability density function (PDF) to find a larva at a distance  $y$  from its birth location. In other words, it is the probability that a larva settles at a given distance from its source population. Measures of natal dispersal (sensu Clobert et al., 2001) are typically determined by the dispersal kernel  $K(x,y)$ , defined as the probability of a larva settling at a distance  $y$ , given that

it was released at a spawning location  $x$ . Dispersal kernels are thus the spatial distributions of dispersed larvae and can be represented in two or three dimensions. The modal dispersal distance from the dispersal kernel has demographic relevance (e.g., population spatial pattern, persistence), while the tail, representing long-distance dispersal, is relevant on an evolutionary level (e.g., genetic mixing, species persistence; Hanski and Gaggiotti, 2004; Steneck et al., 2006).

Currently, the spatial scales of the dispersal of reef fish larvae are estimated using indirect and empirical techniques (Thorrold et al., 2002; Jones et al., 2005; Planes et al., 2009) or modeling approaches (Cowen et al., 2000, 2006; James et al., 2002).

### Empirical approaches

Reef interconnectivity can be empirically estimated by indirect (i.e., population genetics and paternity analysis) or by direct approaches (i.e., tagging/natural markers and larval/settlement observations). Although they differ in the characteristics of the dispersal that they can quantify, empirical methods can provide evidence of (1) *connectivity*, or the strength of the paths between subpopulations (or whether a subpopulation is a source or a sink), (2) *local retention*, or larvae returning to their natal population (sensu Paris and Cowen, 2004), and (3) *self-recruitment*, or strength of replacement paths which are closed loops, typically calculated as the proportion of settlers at a location that were spawned locally (Jones et al., 1999; Swearer et al., 1999; Almany et al., 2007). The latter is a measure of isolation of a subpopulation. If almost all populations within the metapopulation exhibit high self-recruitment, then they will also be characterized by high *local retention* and narrow dispersal kernels (Botfords et al., 2009).

Among the indirect methods, the most commonly used is population genetics that describes *connectivity* by comparing allele frequencies among spatially discrete subpopulations. High levels of genetic similarity between populations suggests high gene flow over time. This is a valuable approach in assessing patterns and degrees of connectivity when methods to directly track larvae are not possible. Indeed, adult populations represent an accumulation of genetic signature from larval sources over time, influenced not only by larval exchange but also by ecological and evolutionary forces. Thus, such estimates of gene flow are an adequate approximation of contemporary levels of genetic connectivity only for species with relatively short life span and strictly sexual reproduction. For reef organisms with overlap across generations, population genetics may not represent present-day connectivity patterns, even for high evolving genes (Hughes et al., 2003). It is also important to note that traditional population genetic F-statistics that have been viewed as a proxy for dispersal over evolutionary time scales are not sensitive to recent changes in gene flow and genetic structure of long-lived organisms that retain the signature of past

events. Other population genetics statistics involving assignment methods can evaluate contemporary connectivity rates without the unrealistic assumptions required by traditional methods (reviewed in Manel et al., 2005). While genetic assignment techniques can link a settler to its natal reef, parentage analysis can identify its actual parent (Jones et al. (2005) provide a promising first example). Parentage analysis yields information on the critical features of dispersal for multiple spatial scales, (Figure 2). The main limitation is performing adequate sampling and collecting a significant proportion of the source adult population and new recruits over the entire potential range of dispersal (although less critical, Planes et al., 2009). Besides genetic methods, direct estimates are possible using geochemical tags recorded from the environment in calcified structures of marine larvae (i.e., otoliths, statoliths, shells). This technique can be used to determine the origin of individuals settling into juvenile habitats, or to examine natal homing of spawning adults that migrate significant distances after settlement (Becker et al., 2007; Thorrold et al., 2001). This approach provides sufficient information to estimate the larval dispersal matrix but is not appropriate to estimate dispersal kernels due to the

relatively large spatial scales of variability of water properties in coral reef environments (Thorrold et al., 1998, 2001). Finally, larval settlement tracking combined with observations of the chemical and physical environments provide accurate estimates of local retention, while allowing quantification of the role of larval behavior in shaping dispersal kernels (critical to calibrate concept-driven biophysical connectivity models). However, this approach requires extensive high-frequency sampling relevant to larval time and space scales (Paris and Cowen, 2004). In addition, local retention is difficult to measure as the reproductive output and the fate of all offspring from a particular population must be known.

### Numerical modeling approaches

Spatially explicit individual based modeling (IBM) has emerged as a key tool for understanding organism–environment interactions (Werner et al., 2001) and is particularly relevant to investigate larval fish fluxes in the complex coral reef ecosystem. Connectivity models aim at predicting the rate of exchange of individuals (i.e., larval fluxes) between the populations forming a metapopulation. Spatially explicit IBMs have become

**Reef Interconnectivity/Larval Dispersal, Figure 2** Empirical estimates of multi-scale larval linkages using DNA parentage analysis of (a) the clownfish (*Amphiprion percula*), (b) between 5 lagoons of Kimbe Is. and (c) from Kimbe Is. to marine reserves (dotted red boxes) proposed in western Kimbe Bay, (d) northeast of Papua New Guinea. Modified from Planes et al. (2009, PNAS).

the most efficient tools in connectivity studies (Werner et al., 2001). The typical output for  $n$  populations is an  $n \times n$  matrix in which element  $(i, j)$  is the probability for an individual to transit from  $i$  to  $j$ . These square matrices are called connectivity matrices or transition probability matrices, each of whose rows ( $i$ ) contain numbers summing to 1. In order to describe a system at ecological scales, the proportion of successful recruits must reflect the recruitment rates (i.e., number of recruits per generation) required to replenish the local population to a minimum of zero growth (Cowen et al., 2006). Such recruitment rates can be estimated a posteriori to match adult mortality rates using simple population growth models (e.g.,  $N_t = N_{t-1} e^{-r_t}$ ). Similarly, demographic connectivity models can be a posteriori scaled by production (e.g., relative spawning biomass per unit population or proportion of adult habitat in each population). Because connectivity models are by nature spatially explicit, it is strongly recommended to couple the Lagrangian tracking algorithm with a geographic information system (GIS). The GIS serves to delineate the source populations as well as the recruitment habitat along an individual particle's path. It is also important to incorporate the uncertainties into the connectivity model (e.g., stochastic Lagrangian model (LSM), stochastic mortality); otherwise, the analytical value of the transition matrices is limited.

The connectivity matrix describes the probability that an individual moves during its pelagic larval stage from the birthplace (or source population) to its settlement location (or sink population) as a settling larva, all in a three-dimensional dynamic system. Such transition probability matrices are of considerable value for metapopulation and genetic studies (Hedrick, 2000) as well as for spatial management and conservation issues (Urban and Keitt, 2001). We show that they also provide a method to quantify the relative influence of biological and physical factors on realized larval dispersal and on levels and spatial patterns of recruits (Paris et al., 2007).

The likelihood of larval exchange from one population to another is represented in a transition probability matrix (Paris et al., 2007). The content of a given matrix element describes the probability of an individual larva, making the transition from its source population and successfully reaching the settlement stage in the destination population. Elements along the diagonal of the matrix (where source = sink) represent self-recruitment within a population. Connections between populations may be represented by several types of matrices (Figure 3): (1) the distance matrix  $d_{ij}$  represents the distances between reefs  $i$  and  $j$ ; (2) the transition probability matrix  $P_{ij}$  represents the probability that an individual larva in node  $i$  at time  $t$  will disperse to node  $j$  at time  $t + k$ , where  $k$  is the pelagic larval duration; (3) the adjacency matrix (or edge)  $A = a_{ij}$  is a binary matrix in which each element is defined as  $a_{ij} = 1$ , if nodes  $i$  and  $j$  are connected, otherwise  $a_{ij} = 0$ . This matrix is mostly used to analyze connectivity networks (Urban and Keitt, 2001). The expected flux  $F$  from node  $i$  to node  $j$  is:  $F_{ij} = S_i / S_{\text{tot}} \times P_{ij}$ , where  $S_i$  is the size of the population

in node  $i$  and  $S_{\text{tot}}$  equals  $\sum S_i$ . We set  $S_i$  to be constant, corresponding with uniform particle release at all locations.

Models of population connectivity emphasize where and how frequently larval linkages occur, how these observed patterns are created, and output spatially explicit transition probability matrices. These connectivity matrices describe the probability that an individual moves during its pelagic larval stage from the birthplace (or source population) to its settlement location (or sink population) and are of considerable value for metapopulation and genetic studies (Hedrick, 2000), as well as for spatial management and conservation issues (Urban and Keitt, 2001). Lagrangian stochastic models (LSMs) are being increasingly applied to track the dispersal of larvae, in which motions at small scales that are not resolved by ocean general circulation models (OGCMs) are usually parameterized (Paris et al., 2005). These include motions due to small-scale currents and random or oriented motions of individual, simulated larvae (Paris et al., 2002; Siegel et al., 2003; Codling et al., 2004).

## Summary

*Coral reefs* are naturally fragmented and the complex interactions of the *reef structure* and their larval behavior with the *circulation* at a series of spatial scales (e.g., *lagoon*, *fringing reef*, and *global circulation*) determine their degree of *interconnectivity*. Typical connectivity in marine populations ranges broadly from demographic to genetic time scales depending on the strength and frequency of larval migrations (Cowen et al., 2000, 2006). However, the spectrum of *connectivity* among *corals* is still uncertain given their longevity and complex reproductive strategies. Indeed, on one hand, a few migrants could suffice to cause demographic connectivity. Conversely, migration could play only a small role on the genetic structure of corals that are highly clonal (i.e., rely mostly on asexual propagation). An integration of numerical and empirical approaches across space and timescales offers the greatest potential for advances in understanding *reef interconnectivity*, requiring more interdisciplinary interaction (Levin, 2006; Werner et al., 2008). Mapping of reef interconnectivity and identifying important coral larval pathways and corridors are keys for their *conservation* (Treml et al., 2008). Indeed, *larval connectivity* helps determine the spacing and size of *marine protected areas* (Pelc et al., 2010), prioritize the protection of critical stepping stone reefs and nodes of populations' networks, and maintain key linkages, enhancing reef resilience to *climate change*-induced stress (Mumby et al., accepted).

## Synonyms

Addressing vessel-grounding impacts; Coral habitat restoration; Coral resource rehabilitation

## Definitions

*Resource restoration.* Resource restoration consists of an attempt to overcome, through manipulation, the factors that impede the natural recovery of an impaired resource.

*Contship Houston.* Contship is an abbreviation for container ship.

*Coral reef restoration.* Reef restoration is the process of returning damaged coral reefs to a state that is functionally equivalent to their uninjured counterparts.

*Emergency restoration.* Emergency restoration involves salvage and reattachment of at-risk coral colonies immediately following a vessel-grounding incident.

## Introduction

Reef restoration is a relatively new and rapidly expanding discipline that attempts to return degraded coral reefs to some degree of their original physical, ecological, economic, and aesthetic functionality on a much-reduced time scale, with the ultimate goal being the full, natural recovery of the impaired resource. The focus of this report is a brief summary of ship-grounding restoration practices in the Florida Keys National Marine Sanctuary (FKNMS), with emphasis on major restoration projects and lessons learned from their implementation. To include examples

of reef-restoration practices in other areas of the world is beyond the scope of this paper. For a global perspective on these and related issues, the following reports are recommended: Hatcher (1984), Salvat (1987), Guzman (1991), Clark and Edwards (1995), Harriott and Fisk (1995), Rinkevich (1995), Heeger and Soto (2000), Jaap (2000), Riegl (2001), Clark (2002), Omori and Fujiwara (2004), Challenger (2006), Kaufman (2006), Jokiel et al. (2006), Precht (2006), and Edwards and Gomez (2007).

## Legal mandate for reef restoration in the FKNMS

Section 312 of the National Marine Sanctuaries Act is a liability provision that authorizes the National Oceanic and Atmospheric Administration (NOAA) to seek damages from those responsible for injuring sanctuary resources (Davidson, 2006). The Act further mandates that NOAA “restore, replace or acquire the equivalent” of injured resources. Thus, coral reef restoration in the NOAA National Marine Sanctuaries is not a management option, but a legal requirement. Decision making for restoring injured reefs in the FKNMS is guided by findings and recommendations of the damage assessment and restoration program (DARP) and is performed by sanctuary personnel following injury assessment of the grounding site.

## Vessel-grounding injuries to coral reefs in the FKNMS

The size and nature of injuries to coral reefs from vessel groundings are influenced mainly by three factors: hull length, weight, and vessel construction material. A general rule of thumb is: the larger the vessel, the greater the injury. For purposes of assigning levels of injury, vessel-grounding incidents in this report are grouped by hull length into three categories: small (<10 m), medium (10–30 m), and large (>30 m). It is reasonable to assume that, when a 122 m (400 ft) steel-hulled cargo ship goes aground on a shallow coral reef, there will be massive destruction of reef resources. Such was the case of the M/V Wellwood that grounded on Molasses Reef, off Key Largo in the Florida Keys in August 1984 (Figure 1). Massive coral colonies were split in half, overturned, and reduced to piles of rubble (Figure 2). The area beneath the ship hull was completely scarified and flattened (Figure 3), leaving the calcium carbonate-based reef foundation (reef framework) fractured and devoid of any living corals (Hudson and Diaz, 1988).

If a large vessel remains aground for a period of days or weeks before its removal, waves and high seas can cause its hull to act like a pestle in a mortar, grinding away additional reef-framework material (Hudson and Franklin, 2005a). Prolonged shading of uninjured portions of the reef by the hull, can, after several weeks, cause shaded corals to bleach by expelling their zooxanthellae (Gittings et al., 1993). The hull of a large vessel can act as a giant plow, pushing up fragmented and intact coral colonies, coral rubble, reef framework, and sand into massive rubble berms on the periphery of the grounding site

**Reef Restoration, Figure 1** The M/V Wellwood, hard aground on Molasses Reef in the (then) Key Largo National Marine Sanctuary, August 1984. (Photo courtesy of FKNMS.)

**Reef Restoration, Figure 2** Living *Montastrea faveolata* dislodged and split in half by impact of M/V Wellwood hull. (Photo courtesy of FKNMS.)

(Schmahl et al., 2006). A large, deep-draft vessel will often strike and shear off corals and sponges and topographic highs of the reef before finally becoming hard aground. In some instances, this inbound path of destruction may stretch for hundreds of meters and may impact several thousand square meters of coral substrate (Schmahl et al., 2006). The kinds of injuries inflicted upon a coral reef when a medium-size (10–30 m in length)

vessel goes aground, while similar to many of those seen in large-vessel incidents, usually differ by an order of magnitude in size and severity.

Total reef injury sustained from intermediate-size vessel groundings rarely exceeds the 100 m<sup>2</sup> threshold. Vessels belonging to the smallest-size category (<10 m) are capable of dislodging and fracturing small coral colonies, scarifying reef framework, and generating small

volumes of rubble. Their injury footprint is usually 10 m<sup>2</sup> or less. Contact of the ship hull with structural elements of the reef is not the only mechanism for destruction in a vessel-grounding incident. Once a ship has grounded, the natural inclination of the captain of any size power vessel is to use the engine(s) to “power off” the reef to deeper water. The end result of this action is often further destruction of the reef and its underpinnings. Water forces acting upon crushed and loosely consolidated reef framework by action of the ship propeller(s) can result in the creation of prop-wash excavation features popularly

**Reef Restoration, Figure 3** Scarified and fractured reef framework at M/V Wellwood grounding site. Note crushed and flattened reef substrate in background. (Photo courtesy of Harold Hudson.)

referred to as “blowholes.” The M/V Alec Owen Maitland, a 47 m (154 ft) oil-supply vessel, grounded on a shallow reef area off Key Largo, Florida, in 1989 (Figure 4) and created a propeller-generated excavation that measured approximately 2.5 m deep by 25 m in diameter. This type of injury is inherently unstable since the crater is subject to further erosion by storm waves, as evidenced during passage of Hurricane Andrew in 1992 (Hudson et al., 2008). In addition, natural sediment infilling creates a substrate of shifting reef sand within the blowhole that is unsuitable for coral attachment. While prop-wash excavations can occur in medium-size groundings on coral reefs, they are conspicuously absent from those in the smallest vessel-size class.

Another injury feature commonly associated with vessel groundings on coral reefs is the presence of anti-fouling bottom paint within the impact area. Pressure and friction contact of the vessel hull with reef substrate often heats and peels away patches of bottom paint, embedding paint into the surface of impacted reef framework. While present to some degree on most grounding sites, dislodged bottom paint on large-vessel grounding sites is usually abundant and contaminates significant areas of reef substrate. Due to its toxic nature, this material should be removed and safely disposed off on land as soon as possible after the grounding.

#### Emergency salvage (triage) of corals in the FKNMS

After an assessment has been conducted to document and quantify the nature and extent of the grounding injury (Hudson and Goodwin, 2001), emergency salvage of dislodged coral colonies and reef-framework fragments is implemented. The surviving colonies are removed from

**Reef Restoration, Figure 4** M/V Alec Owen Maitland, hard aground in October 1989 on an unnamed bank reef south of Carysfort Reef in the (then) Key Largo National Marine Sanctuary. (Photo courtesy of FKNMS.)

**Reef Restoration, Figure 5** A grounding-dislodged and fractured colony of *Diploria* sp. Both living and dead coral elements are routinely collected and cached onsite by DARP personnel for use in rebuilding lost reef topography. Loose, on-site calcium-carbonate rock is highly prized as a material for rebuilding reef structure and, when available, is preferred over quarried limestone rocks and boulders. (Photo courtesy of FKNMS.)

loose rubble and sand and placed upright. It may be necessary to cache these at-risk corals in a suitable area near the site, or even off-site, until primary structural restoration has been completed. If the colonies are relatively small (<15 cm, or 6 in.) in diameter and in imminent danger of being lost to storm surge or high wave energy, the best emergency-salvage option may be to reattach them immediately to adjacent uninjured reef substrate. Dislodged, nonliving reef-framework fragments (Figure 5) are usually cached in sand areas adjacent to the injury site.

#### Restoration of small- to medium-size grounding sites in the FKNMS

When restoring reefs injured in small- to medium-size vessel groundings, the most effective strategy is often limited to simple reattachment of broken and dislodged live coral colonies and fragments back onto the grounding site. Epoxy cement and related epoxy-putty compounds are usually the most cost-effective adhesives when reattaching small-diameter (10 cm or less) colonies or live coral fragments (Jaap et al., 1996). Heavy-duty electrical tie wraps can also be used to reattach pieces of small (>30 cm) fragments of live branching corals to a parent colony or to a dead coral outcrop. Reattachment of coral colonies and dislodged reef framework greater than 10 cm is usually more cost-effective with Portland cement. Hudson and Diaz (1988) provide a basic formula and application instructions for a quick-setting (4–6 min) adhesive that combines Portland cement with molding plaster (Figure 6). Portland cement can also be combined 50/50% with construction-grade sand to produce

**Reef Restoration, Figure 6** A broken branch of live elkhorn coral, *Acropora palmata*, reattached to the reef with quick-setting Portland cement. Note gray mass of cement under coral at lower right. Another reattached fragment can be seen above, beneath the diver's swim fins. (Photo courtesy of Jeff Anderson.)

a cement grout that will remain workable under water for 30 min or more (Figure 7).

It is usually impossible to determine the original position, sizes, and number of dislodged reef elements on any but the smallest grounding site. By surveying unimpacted coral reef communities (control or reference areas) that are immediately adjacent to the injury site, number and size of reef outcrops, coral size, density, and species composition can be reasonably estimated. These data are routinely collected as part of grounding-injury assessment protocol and thus serve a dual purpose to aid researchers in reattachment of dislodged reef biota and recreation of topography that approximates pre-grounding conditions.

#### Restoring large-size grounding sites in the FKNMS

Whereas many of the injuries to reefs resulting from small- and medium-size vessel groundings may be

**Reef Restoration, Figure 7** Three intact specimens of knobby cactus coral, *Mycetophyllia aliciae*, one smooth brain coral, *Diploria clivosa* (touching diver's finger), and a small fragment of mountainous star coral, *Montastrea faveolata* (between largest and smallest *M. aliciae*) cemented to a fiberglass "tent" with a 5 cm (2 in.) thick layer of 50/50% Portland cement and sand grout. (See Anderson et al., 2008; photo courtesy of Jeff Anderson.)

addressed through reattachment of broken and dislodged corals, there are incidents where the destruction of reef elements is so catastrophic that natural recovery is unlikely to occur. Recent history has demonstrated that these major grounding sites on shallow coral reefs in the FKNMS will continue to degrade and, if left untreated, will worsen considerably as a result of high-energy (hurricane) impacts (Hudson and Franklin, 2005a, b; Hudson et al., 2008). Moreover, even without a disruption by hurricanes, the injured reef and habitat that it once provided would not be regenerated for decades (Gittings et al., 1993; Precht et al., 2001).

Stabilization and reconstruction of crushed and flattened reef framework are required to allow eventual natural recovery of these grounding sites. To implement a reef-repair project for an injury of this magnitude requires numerous state and federal permits and a highly detailed engineering plan. Offsite and onsite construction and the use of a barge, crane, tug, and commercial divers to place and secure reef-restoration components are also required (Figures 8–12). FKNMS (DARP) personnel provide technical oversight of these projects.

Locally quarried limestone boulders, concrete, and fiberglass-reinforcement rods are currently the primary materials of choice to fabricate and install reef-replacement structures (Hudson and Franklin, 2005a, b). For additional information on coral reef restoration and monitoring in the Florida Keys National Marine

Sanctuary, the reader is directed to the following NOAA website: <http://noaa.sanctuaries.gov>.

### Lessons learned

In terms of lessons learned, hurricanes are quite literally "a force to be reckoned with." In 1992, Hurricane Andrew caused severe collateral injury to the 1989 M/V Alec Owen Maitland grounding site (Hudson et al., 2008). Failure of critical structural-repair elements at the container ship M/V Contship Houston restoration site during passage of Hurricane Georges in 1998 focused attention on the need for adequate consideration of long-term stability of reef-restoration components (Schmahl et al., 2006). Hurricane Georges also exposed another type of structural deficiency at the Wellwood grounding site off Key Largo. In 1998, Hurricane Georges removed nearly all of the hard corals that had been transplanted at the grounding site in 1985 (Hudson and Diaz, 1988; Hudson and Franklin, 2005b). A post-hurricane survey (JHH, unpublished data) revealed that more than 90% of transplants were dislodged when hurricane-force waves and ground swells excavated 14 large craters within the main injury area.

With the exception of the M/V Contship Houston site, restoration of the above grounding sites was delayed by 5 years or more. In the interim, hurricane strikes resulted in considerable expansion of the areas of original injury. It can be reasonably assumed that the significant added destruction inflicted by these storm events resulted in increased restoration costs.

**Reef Restoration, Figure 8** One of 40 900 kg (20,000 lb), pre-cast concrete reef armor units installed at the M/V Maitland grounding site in 1995. (Photo courtesy of FKNMS.)

**Reef Restoration, Figure 9** Seaward edge of a Reef Armor Unit at the M/V Maitland site, 10 years after installation. The module surface is completely coated with a thin layer of crustose coralline algae. It is widely recognized that hard-coral planulae have a strong preference for settling on substrates that have been pre-conditioned by certain species of this lime-secreting plant. Blade fire coral, *Millepora complanata*, left of center, and a brain coral, *Diploria labyrinthiformis*, center, have recruited to the thin, hard rind of crustose algae. Note profusion of gorgonians (soft corals), primarily *Pseudopterogorgia americana*, that have colonized crevices along the base of the module. (Photo courtesy of Jeff Anderson.)

## Conclusions

Restored vessel-grounding sites in the FKNMS are slowly recovering, as evidenced by FKNMS monitoring reports on recruitment of crustose coralline algae, soft and hard

**Reef Restoration, Figure 10** Photo shows one of 22 Reef Replacement Modules prior to installation on Molasses Reef in 2002 at the M/V Wellwood grounding site off Key Largo. The structures were designed to replicate reef topography and create habitat for cryptic biota. A reef "cave" was incorporated inside each module as a refuge for cryptic reef dwellers. FKNMS personnel fabricated all units in Key Largo using a custom mold, poured concrete, fiberglass-reinforcing rod, and locally quarried oolitic-limestone boulders. This photo shows how the boulders are embedded into the module base. (Photo courtesy of Jeff Anderson.)

corals, sponges, mollusks, crustaceans, fish, and other reef biota onto and around restoration structures. Whether these restored areas will eventually be transformed to pre-grounding conditions is time-dependent, and the answer will most likely come from the next generation of coral reef scientists.

**Reef Restoration, Figure 11** A group of Reef Replacement Modules at the M/V Wellwood grounding site inside the largest of 14 hurricane-excavated craters. A barge crane lowered the modules to the seafloor, and commercial divers guided the units into position as shown. A special low-washout concrete mixture was then delivered via pump and hose to fill the craters, locking the Reef Replacement Modules securely into the reef. Small limestone boulders (dressing stones) were quickly embedded into the fresh concrete around the modules to create additional substrate rugosity. (Photo courtesy of FKNMS.)

**Reef Restoration, Figure 12** Photo shows Reef Replacement Module #8-A at the R/V Wellwood restoration site on February 17, 2006. Eight 5 cm (2 in.) long, branch tips of staghorn coral, *Acropora cervicornis*, were transplanted on this structure on October 29, 2003. Note that crustose coralline algae, a critical pioneer biofouling component that has been shown to induce recruitment of scleractinian coral planulae, have coated the entire exposed surfaces of limestone boulders. Also highly visible is *Dictyota* sp., a seasonally abundant brown macroalgae (olive-green overgrowth in this view) that has temporarily colonized much of the structure. Compare with [Figure 10](#) and note that only the limestone boulders project above the reef substrate. (Photo courtesy of Jeff Anderson.)

## Synonyms

Reef architecture; Reef platform structure

## Definition

Internal structural or architectural elements of a reef system or buildup.

## Introduction

Since the recognition of subsidence as a control on coral reef formation (Darwin, 1842) and the realization of the role of glacial sea-level oscillations and low stands in reef development (Daly, 1910), coral reefs have provided a focus for marine biogeological research.

One of the principal factors that appears to determine the growth and morphology of reefs is the available space (termed accommodation), which often results from the interaction of subsidence and sea-level change. Sea-level fluctuations occur through time and are important primarily because the sea surface determines the absolute accommodation for a given reef, so that a reef growing during a period of sea-level rise will be able to build upward as space is created above it. Keep-up, catch-up, and give-up responses are possible as the reef strives to keep pace with sea-level rise (Davies et al., 1985; Neumann and Macintyre, 1986). If the reef grows to the sea surface, thereby occupying all the available accommodation, it can no longer accrete vertically and may begin to build laterally, leading to different patterns of internal architecture or reef structure.

Another factor is the availability of suitable substrate for reef growth. Corals or other colonizing communities tend to become established on rocky substrate projecting above sediment-covered marine surfaces, so that reefs may return to preferentially colonize the buildups left by previous cycles of reef growth, forming complex architecture through time. Other important controls on reef growth include sea temperature (18–30°C waters of tropical/subtropical latitudes), nutrient levels, light and turbidity, wave and tidal energy, salinity and water depth (<30 m), and the destructive energy and frequency of storms.

## Reef morphology

Reefs have three main morphological elements: forereef, reef, and backreef, each with its own biota and sediment types. The forereef slopes seaward and is composed of debris or reef-building organisms; the reef is narrow-crested or a flat-topped zone where calcareous reef framework builders are active, often capped by an algal rim found commonly beneath the breaker zone; and the backreef consists of coral communities and reef debris swept landward behind the reef, including sand sheets to mud deposits in lagoonal environments. This zonation has been described for many reefs (e.g., Florida reefs: Ginsburg and Shinn, 1964; Western Atlantic reefs: Rutzler and Macintyre, 1982; Indo-Pacific reefs: Montaggioni, 2005; U.S. reefs: Reigl and Dodge, 2008; Australian reefs: Hopley et al., 2007). Coral community structure is influenced by depth and interaction between physical

disturbance (due to storms and/or wave action and currents) and recovery time, causing (with other factors) considerable variation between reef systems (e.g., Grigg, 1994). Thus, forereef slopes may have excellent coral cover (Belize barrier reef, Caribbean Sea: Rutzler and Macintyre, 1982), or be mantled by reef debris (fringing reef at Galeta Point, Panama: Macintyre and Glynn, 1976), while still others have only sparse, robust coral cover (Ningaloo fringing reef, eastern Indian Ocean: Collins et al., 2003). At Carrie Bow Cay, Belize, the profile is outer forereef with steep inner slope, sand trough, and outer coral ridge; inner forereef with spur and groove structure, narrow intertidal reef crest; and shallow backreef with massive corals, pavements, and rubble accumulations (see Rutzler and Macintyre, 1982, Figure 31).

Within the morphological zones of the reef, different coral communities are established and also interact with physical processes, so that both the communities and the sedimentary products (essentially reef framework and reef-derived detritus, termed facies) are preserved. In a wide-ranging core study of Indo-Pacific reefs (Montaggioni, 2005), seven frameworks and three detrital facies were identified on the basis of the nature and growth shapes of dominant framework builders, and on that of the texture of sediments, respectively. Framework facies in high-hydrodynamic energy settings were dominated by coralline algae and robust-branching corals. In moderate energy environments, these were replaced by domal, tabular branching, and arborescent corals, whereas sheltered areas included arborescent, foliaceous, and encrusting coral species.

Traditionally, reefs have been grouped into fringing reefs, barrier reefs, atolls and pinnacle or patch reefs, and bank-barrier reefs. Observations during the voyage of the Beagle in 1837 led Charles Darwin to formulate his theory of atoll evolution based on volcanic island subsidence, with a fringing reef ring evolving to a barrier reef as a lagoon developed behind the encircling reef, and finally, as the crest of a volcano submerged, an atoll with a central lagoon (Darwin, 1842). This atoll-forming sequence continues by progressive plate subsidence away from hot spots along seamount chains, until permanent reef drowning occurs at the “Darwin Point” (see Grigg, Figure 2 in *Hawaiian Emperor Volcanic Chain and Coral Reef History*), beyond which atolls drown and become guyots. Patch reefs also evolve as ring structures formed by leeward accretion of detritus and progradation to culminate in atolls (Fairbridge, 1950), or wave-planated banks may be colonized by peripheral reefs to form atolls (Purdy, 1974).

## Controls on reef architecture

A number of interacting controls on growth rates and growth styles of reefs have been identified (e.g., Davies and Marshall, 1980; Hopley, 1982), which together determine overall growth responses and patterns of internal structure or reef architecture, such as subsidence rates,

preexisting topography, Holocene (last 10,000 years) sea levels, biological and ecological factors, and environmental history during reef development.

Subsidence rate varies with plate tectonic setting and can be significant to negligible at Holocene timescales. Highest rates are experienced on oceanic plates, for example, as volcanic island chains progress away from mid-oceanic hot spots, influencing atoll formation as foundations subside. Similarly, subsidence is usually significant at active plate margins, whereas mid-plate and stable passive margin settings have low subsidence rates.

The amount of subsidence controls the nature and elevation of the preexisting (or antecedent) topography on which a newly established reef grows. This topography reflects the type of substrate being colonized, and its deposition/erosion history, and preferentially colonized regions (usually topographic highs) are often reflected as prominences in subsequent reef growth and architecture.

Holocene sea-level history is a fundamental process influencing reef growth, and is the latest major episode in the glacially forced sea-level changes that have affected global climate and coral reef growth for the last 800,000 years and beyond, following Milankovitch's (1941) astronomical theory. Aside from ice cores and the marine sediment isotope record, many of our global sea-level change records come from coral reef records (Davies and Hopley, 1983; Fairbanks, 1989; Hopley et al., 2007, Chapter 3; Lighty et al., 1982; Toscano and Macintyre, 2003). Following the end of the last glaciation, when sea level stood at  $-120$  m at ca. 18,000 years ago around many continental margins, there has been a general sea-level rise to reach present level, albeit with rate changes relating to pauses and meltwater pulses, and culminating (in some parts of the world, e.g., Australia) with sea level 1–2 m above present some 6,000 years ago, followed by a fall to present level. As new potential habitat has become available around the continental margins, coral reefs in settings from oceanic islands to outer shelf to the coast have grown vertically to track the rising near-surface "reef growth window" of suitable light and temperature conditions favored by corals and their photosynthetic zooxanthellae.

### Models for reef architecture

The degree to which a reef is able to successfully track sea-level rise is indicated by keep-up, catch-up, and give-up responses, with those in the latter group becoming drowned reefs or platforms. Within a single reef, a number of growth stages may be recognized, such as colonization, rapid vertical accretion, catch-up growth with the stages recorded in accumulation rates and different coral framework communities (e.g., branching vs. head coral framework). In shallow tropical reefs (Neumann and Macintyre, 1986, Figure 3), these growth patterns are Keep-up reefs: shallow, frame-building communities throughout sea-level rise (windward shelf setting-fringing to barrier reef); Catch-up reefs: initially shallow, then deeper, and finally shallowing-upward

sequence (protected shelf, backreef patch, or bank barrier); Give-up reefs: reefs founder as reef growth lags behind sea-level rise and declines/ceases, becoming drowned or relict (deep shelf setting-deep mounds).

One approach taken to describe the variation between fringing reefs was based on the nature of the antecedent surface that they are established over as well as the proportion of framework and detrital sediments within the reef structure (Hopley and Partain, 1987).

The first of three types was simple reefs that are established while sea level is still rising over rocky foreshores. Growth is primarily vertical and composed of framework; however, once the reef surface reaches sea level, as for instance during a still stand, minor outward growth may occur. Reef-flat development tends to be restricted. The second type of fringing reefs has developed over a gently sloping substrate, particularly, older Pleistocene reefs. The reefs were initiated offshore when sea level was lower. The framework units are then attached to the shoreline through interfingered terrigenous and detrital backreef infill. The final fringing reef type is developed over preexisting sedimentary deposits including fine muds. Progradation of the reef is often rapid over the preexisting structure with the reef-flat framework forming a thin veneer (generally  $<4$  m thick) over carbonate and terrestrial debris (Hopley and Partain, 1987). This scheme was further developed by Smithers et al. (2006) and Hopley et al. (2007).

Fringing reefs generally fit within one of these three morphological types, but morphology does not indicate the mode of reef evolution. The two very important factors that affect the evolution of the reef are sea-level change and tectonic stability. These two factors are interrelated as vertical tectonic movement is equivalent to a relative sea-level change at a given reef location.

Kennedy and Woodroffe (2002) described six models (A–F) of fringing reef development based on chronostratigraphic data expressed as isochrones (time lines) in thousands of years BP. These models are based on available accommodation, as follows:

Model A: Reef accretion is vertical growing in keep-up or catch-up mode.

Model B: Reef accretion is lateral having established at a level with little or no vertical accommodation.

Model C: Lateral reef accretion occurs concurrently with deposition of non-reefal mud in the forereef zone.

Model D: Episodic progradation model.

Model E: Reef accretion is initially focused offshore creating a shallow landward lagoon.

Model F: The offshore reef structure is formed by storm processes and is essentially a rubble pile. Some landward movement of this rubble pile may occur as sediment is reworked landward.

These classifications of fringing reefs have been widened for the different reef morphologies known in the Indo-Pacific domain (i.e., fringing and barrier reefs, platform reefs, and atolls: Montaggioni, 2005) to five anatomical

types of reef system based on dominant depositional process, reflected to some extent in seismic architecture.

**Balanced aggrading–onlapping model:** Deposition within lagoons operated at rates close to those of the adjacent reef rim allowing the different parts of the system to reach sea level at the same time. There was a fine balance between reef rim growth through aggradation and backreef accumulation through onlapping. The dominant process refers to balanced aggradation–onlapping (Model A of Kennedy and Woodroffe, 2002).

**Seaward prograding model:** This relates to reef systems that developed seaward by lateral accretion of the forereef. They started to grow in settings where vertical accommodation was limited or missing. Such Holocene reefs mostly developed close to the shore when sea level was around its present-day position. Referring to Models B and C recognized by Kennedy and Woodroffe (2002), they are common in inner shelf sites (see Montaggioni, 2005).

**Back-stepping model:** Lateral backward accretion can occur episodically; in this case, the reef develops through coalescing of offshore patches onto the forereef zone from framework growth and/or sediment infill (Model D of Kennedy and Woodroffe, 2002; see Montaggioni, 2005).

With back-stepping reef anatomy, reef initiation occurred below modern sea level at depths where the rates of reef aggradation during the early Holocene times were not efficient enough to fill up available accommodation. The landward migration of accretion centers is assumed to result from the specific adaptation of coral communities to local environmental changes, and coral communities would be forced to displace landward to find habitat suitable for sustained growth (Engels et al., 2004).

**Unbalanced aggrading–downlapping model:** This anatomy relates to reefs that comprise a well-developed, outer rim enclosing a depressed backreef area forming through multiple depositional processes. During the earlier times of inundation, the backreef zones probably were open systems (lagoons) in which sediment accumulation was continuously disrupted by water circulation, with deposition of coral gravel. As the reef margins developed vertically, water agitation within the backreef areas decreased progressively and the sedimentation changed to sand and/or muddy sand. After the sea-level transgressive phase ended around 7,000 years BP, most of the reef rims that developed through keeping pace with sea level formed protecting barriers, thus favoring trapping of sediments

**Reef Structure, Figure 1** Contrasting sea-level curves, reef response, and reef structure for (a) Australian and (b) Caribbean reefs. (From Hopley et al. [2007, Chapter 11].)

within backreef environments, and this explains why the main phase of backreef infill started at around 7,600 years BP on many reefs (see Montaggioni, 2005).

Backreef sediment sheets accumulate as downlapping clinoforms at the inflection of slope between the rim-lagoon transitional slope and lagoon floor settings.

Unbalanced aggrading-onlapping model: Backreef deposition can also occur through onlapping beds caused by termination of gently dipping to subhorizontal sheets against steeply dipping antecedent substrate or flanks of intralagoonal coral patches; the isochrons are parallel to the lagoon floor surface. Correlative to backreef infilling,

vertical accretion of the reef margins occurred until the margin top reached the present sea-level position; then, the former prograded backward over early deposited backreef sediment beds. According to their initial depth and width and the sedimentation rates, the backreef bottoms remained either under subtidal conditions, filled up completely or passed through intertidal to supratidal deposits. For examples, see Montaggioni (2005).

Differences in reef growth and structure result from contrasting patterns of postglacial sea-level rise, such as between Indo-Pacific and Caribbean reefs (Neumann and Macintyre, 1986; Toscano and Macintyre, 2003; Hopley

Reef Structure, Figure 2 Comparative architecture of Ningaloo, Houtman Abrolhos, and Scott reefs.

et al., 2007). While Caribbean reefs have steep crestral profiles reflecting vertical growth and rising sea levels in the last 6,000 years, Indo-Pacific reefs responded to slowly rising and then stable or slowly falling sea levels by lateral growth and expansion, becoming more flat topped. These contrasting patterns of reef growth are summarized in Figure 1.

### Setting, antecedent topography, subsidence and sea level change in reef architecture: a “three reefs” comparison

Three reefs with differing morphology and setting which are well known in terms of sea level history, seismic and subsurface architecture, preexisting substrate and subsidence are the Ningaloo fringing reef, the Houtman Abrolhos reefs (shelf edge reefs with atoll-like form), and Scott reef (an isolated platform with circular to arcuate reefs). The first two are in tectonically stable settings, while the third has undergone significant subsidence at Holocene timescales (Collins et al., 1993, 2003; Collins, 2009). Both tectonics and setting have influenced the elevation of the preexisting topography of the last interglacial reef (formed ca. 125,000 years ago when sea level was some 4 m above the present level along the western margin of Australia; Lambeck and Nakada, 1990) so that the pattern of Holocene reef growth and structure reflects these controls.

The Ningaloo fringing reef at latitude 20–22°S records Holocene and last interglacial phases of reef growth, but the last interglacial reef was widespread here as a fringing system whose elevation was 2–3 m above that of the Holocene transgression. Without subsidence, this coastal setting provided only limited accommodation for Holocene reef development. Consequently, the Holocene reef is relatively thin, and mantles the last interglacial reef, which provided a template for Holocene growth (Figure 2).

The outer shelf Houtman Abrolhos platforms (at 28–29.5°S) aggraded in a tectonically stable environment with the last interglacial stage of reef growth forming central platform emergent reefs, present as islands 2–5 m above sea level today. Rising Holocene sea levels partially drowned the old reef topography which was colonized in eroded portions of the last interglacial substrate, building a 10 m thick Holocene windward reef, but most Holocene reef development took place by leeward platform growth in wave-protected environments in the lee of the last interglacial platform islands, filling the entire 40 m of available accommodation and building a system of Holocene leeward reefs. The distinctive atoll-like form of the Houtman Abrolhos reefs reflects the vertical and lateral (last interglacial and Holocene) stages of reef development shown in Figure 2.

At Scott reef (at 14°S), an isolated reef, which overlies a carbonate platform, seismic profiles reveal a last interglacial reef system, but reefs, which apparently grew to sea level, are now 30 m below the present sea level,

indicating significant subsidence. Holocene reefs grew in the accommodation provided by subsidence as saucer-shaped reefs (marginal reefs with central lagoon) and are up to 35 m thick. The combination of subsidence and recurring sea-level high stands caused repeated reef stacking as a sustained pattern of reef growth (Figure 2).

### Summary

Reefs grow with distinctive morphologies such as fringing, barrier, platform, and atoll forms, preserving internal patterns of reef communities whose ecology records much of their history. They respond to important controls such as substrate, subsidence, and sea-level change, and this is reflected in their architecture. As repositories of biodiversity and records of past climates, they deserve special attention and high conservation status in our world of changing climate (see Wilkinson, 2008), increasing storms, sea-level rise, bleaching, and ocean acidification.

## REEF TOPOGRAPHIC COMPLEXITY

David G. Zawada

U.S. Geological Survey, St. Petersburg, FL, USA

### Definitions

*Topographic complexity* is the three-dimensional arrangement of structural features over the seafloor surface, spanning all spatial scales.

*Rugosity* is an estimate of topographic complexity based on a single measurement scale.

*Roughness* is an estimate of topographic complexity based on measures spanning a range of spatial scales and pertains to the textural characteristics of a surface.

### Introduction

Coral reefs are among the most topographically complex biogenic structures in the sea. Topographic complexity (TC) exists on all spatial scales and influences a wide range of biological, chemical, and physical aspects of a coral reef system, such as water flow (Munk and Sargent, 1954; Monismith, 2007; Nunes and Pawlak, 2008) and, consequently, nutrient uptake and mass transfer rates (Shashar et al., 1996; Hearn et al., 2001), species richness and biomass (Friedlander and Parrish, 1998; Idjadi and Edmunds, 2006), and both refuge (Steele, 1999) and larval-settlement space (Idjadi and Edmunds, 2006). Because of these impacts, quantifying and mapping the spatial variability in TC is important to understanding the functioning of a coral reef ecosystem.

Two frequently used indices of TC are rugosity and roughness. Although both indices are derived from vertical-relief measurements of the reef surface, they have different computational methods, interpretive value, and limitations. The resolution of the requisite topographic data depends on the scientific question of interest. For example, studying the effects of TC on the boundary-layer flow over a single coral head would require fine-scale ( $\leq 1$  cm) horizontal and vertical topographic measurements. However, the effects of TC on reef-fish community structure could be ascertained using coarser measurements (meters horizontally and centimeters vertically), but with a larger spatial extent. Regardless of the measurement scale, the same respective algorithms apply for estimating either rugosity or roughness.

### Reef Surface Rugosity

Rugosity is most often derived from vertical profiles of surface relief, measured by placing either a chain or a profiling gauge in contact with a surface, following protrusions and crevices (McCormick, 1994; Frost et al., 2005). The ratio of the overall chain length to the straight horizontal distance between the ends of the chain on the reef is the “rugosity index,” which ranges from 1 for a horizontal line to  $\infty$  with increasing vertical relief.

The limitations of this technique are well documented (e.g., McCormick, 1994; Commuto and Rusignuolo, 2000; Pittman et al., 2009) and include the absence of an upper limit, a measurement-scale bias (chain-link size or pin-spacing in the gauge), and an orientation bias for nonisotropic surfaces (i.e., surfaces for which the vertical profile changes with the direction of the transect, such as along versus across the reef crest). The rugosity concept has been extended to two dimensions by dividing the surface area of a given region by its bounding horizontal area (Dahl, 1973; Brock et al., 2006). The result is a dimensionless index, also ranging from 1 to  $\infty$ , which indicates the increase in surface area relative to the underlying horizontal plane. While free of orientation bias, this approach shares the other shortcomings of profile rugosity.

Regardless of the approach taken, profile or area, the lack of an upper bound and a clear frame of reference makes physical interpretation and cross-study comparisons tenuous at best. Interpreting rugosity values is further hampered by the lack of a standardized measurement protocol. Both sample size (i.e., chain length or region size) and sample resolution (i.e., chain link size, pin spacing, etc.) significantly affect the resultant rugosity index. Additionally, if measurements are made over a nonisotropic surface, then the rugosity index will be biased by the orientation of the chain or profiling gauge on that surface. Finally, there is little discriminatory power to the rugosity index because it is an aggregate quantity. One cannot distinguish between a single, large vertical excursion and multiple, smaller ones with an equivalent composite contour length or surface area. Collectively, these shortcomings diminish the effectiveness of rugosity as a descriptor of TC.

### Reef Surface Roughness

Roughness is typically derived from digital elevation models (DEMs), constructed from topographic data over a given area. Acquiring such data in situ on submeter scales is hindered by the lack of suitable tools. Work at this fine scale tends to be performed in the laboratory, where topography can be measured using a two-dimensional profiling gauge, consisting of an array of equally spaced, moveable pins (Carleton and Sammarco, 1987) or an X-ray computed tomography technique (Kaandorp et al., 2005). For larger areas, possibly covering tens of square kilometers, data collection can be performed using either light detection and ranging (lidar) (Brock et al., 2004) or multibeam sonar systems (Piniak et al., 2006).

Although various spatial statistics could be used to estimate roughness, fractals represent a particularly robust approach, providing both a firm geometric framework and assessing the extent of surface irregularity over a range of measurement scales. In classical Euclidean geometry, a plane has a dimension of 2 and a solid has a dimension of 3. These objects are perfectly smooth and have zero roughness. Fractal surfaces, however, lie between these extremes and have noninteger dimensions.

Fractals exhibit power-law scaling, meaning that spatial variations observed at one scale are replicated or are at least statistically similar to those at another scale (Mandelbrot, 1977). Fractal theory provides the basis for quantifying such multiscale variability or roughness, which is expressed in terms of the fractal dimension,  $D$ . Mandelbrot (1977) provides an overview of fractal geometry and its relevance to natural objects.

Although the fractal approach is more powerful and descriptive than the rugosity index, these benefits impose costs in terms of data requirements, algorithm complexity, and computing resources. Topographic data must span at least two orders of magnitude to validate power-law scaling. Algorithm selection is critical, because some procedures suffer from mathematical instability (Zhou and Lam, 2005). Finally, programming skill is required to effectively implement the chosen algorithm, both in terms of computational efficiency and data management.

Zawada and Brock (2009) provide an example of mapping reefscape roughness with a fractal technique. Using a DEM with 1 m spatial resolution that was derived from lidar bathymetric measurements, those authors investigated the zonation in roughness over a 5 km  $\times$  5 km portion of the reefscape in Biscayne National Park, Florida, USA (Figure 1a). That area contains carbonate sand, seagrass meadows, and a variety of reefal habitats. The study site was divided into 500 m  $\times$  500 m tiles, and the surface roughness was computed as the fractal dimension,  $D$ , for each tile (Figure 1b). The zonation patterns based on  $D$  correspond well with the geomorphic domains of each reef type at this site. Mature, large, shallow, flat-topped patch reefs (region labeled “1” in Figure 1b) have less roughness than the deeper knoll-shaped patch reefs (diagonal band of orange tiles in Figure 1b) or the crest of Pacific Reef (labeled “2” in Figure 1b), which mainly consists of encrusted, dead colonies of Holocene *Acropora palmata* and rubble. To provide a visual cue for the relation between reefscape roughness and the corresponding fractal characteristics, two regions (labeled “1” and “2” in Figure 1b) are presented both in plan view and in a three-dimensional perspective view (Figure 2a–d). Region “1” lies within the shallow patch-reef zone, and Region “2” covers the crest of Pacific Reef. The textural differences corresponding to increasing fractal dimension are most apparent in the perspective views (Figure 2b and d). Large, comparatively smooth patch reefs with high relief give way to smaller, lower relief, more numerous and jagged benthic features with increasing  $D$ . Visually, benthic substrates with larger fractal dimensions look rougher.

### Summary

Topographic complexity is a fundamental structural property of coral reefs that exists on all scales and affects a multitude of processes. Rugosity and roughness are the two most commonly used measures of TC. Being based on measurements across the reef surface, both indices

**Reef Topographic Complexity, Figure 1** Study site submerged topographic and roughness maps (adapted from Zawada and Brock, 2009). (a) This 5 km × 5 km area in the southern portion of Biscayne National Park, Florida, was chosen because of its mixture of reef types and the availability of a high-resolution DEM. (b) The study site was divided into 500 m × 500 m tiles. Roughness, expressed in terms of fractal dimension, was computed for each tile. For reference, the 7-m contour is plotted on top of the roughness map. The tiles labeled "1" and "2" indicate the two regions depicted in Figure 2.

**Reef Topographic Complexity, Figure 2** Detailed view of two 500 m  $\times$  500 m tiles (adapted from Zawada and Brock, 2009). The tiles indicated in Figure 1 are depicted both in plan and perspective views to convey a visual sense of roughness corresponding to their respective fractal dimensions. Panels a and b correspond to Tile 1, which lies in the shallow patch-reef zone. Panels c and d correspond to Tile 2, which is situated on the crest of Pacific Reef.

necessarily underestimate TC. Contributions from the undersides of corals and ledges are ignored, as are the insides of caverns within the reef. Rugosity is expedient with respect to data collection and processing. However, it possesses significant mathematical and implementation deficiencies, which impede interpretation beyond generalized statements of “more or less rugose” within a specific study. Although more computationally arduous, roughness overcomes these limitations and represents a holistic metric for TC.

## REEF TYPOLOGY

Serge Andréfouët  
 Institut de Recherche pour le Développement, Anse Vata,  
 Noumea, New Caledonia

### Definition

Typology is the study of types. It is related to the classification of objects in categories according to a series of characteristics relevant for a given purpose, and the methods to achieve it. Reef typology is thus about the definition of categories of reef objects useful to study a particular aspect of coral reef processes.

### A variety of reef-related typology

Definition of a reef typology implies the selection of a number of criteria. Scales, in time and space, are key

criteria to define a typology useful to study the processes of interest (Hatcher et al., 1987; Hatcher, 1997). Reef typologies can be built for the different scales, entities, and components of the reefs, and across different scales as well.

For instance, at the finest level, taxonomy of species will look at the categories of the different living organisms based on evolutionary criteria (e.g., Veron, 1995 for corals). But in another context, organisms may be classified based on functional properties such as their metabolism. Functional typology will consider, for instance, if organisms calcify or not, if they are autotrophs or not, if they harbor symbionts or not, or where they fit in a trophic chain.

At another level of organization, coral reef habitats can be categorized using information on benthic cover (Mumby and Harborne, 1999; Diaz et al., 2000; Andréfouët et al., 2003), three-dimensional architecture, rugosity, and depth (Purkis et al., 2007). Productivity can also be an interesting criterion to classify reef zones and habitats (Smith, 1978; Kinsey, 1985). Hydrodynamics and residence time of waters have also been used to classify atoll lagoons (Andréfouët et al., 2001a).

At reef-scale, coral reefs can be described according to the diversity of habitats found on the reefs. Another common typological criterion is geomorphology, which accounts for reef shapes, exposures to hydrodynamics, position relative to nearby land masses, and depth (Stoddart, 1965; Hopley, 1982; Andréfouët et al., 2001b).

As an example of multi-scale entity, it is now common practice to define reef habitats hierarchically, by taking into account information on geomorphology, benthic cover, architecture, depth, and taxonomy of the structuring communities (corals, algae, seagrass). However, not all attributes of such a typology are easily available at all locations. Habitats can be resolved at local and global scale using geomorphological criteria and remote sensing observations (Diaz et al., 2000; Andréfouët et al., 2006), but other criteria require in situ sampling and observations to be accurate.

Obviously, the classifications criteria above are selected for particular thematic purposes. For instance, habitats can be defined and mapped to optimize conservation planning and fishery management at ecological scales (Dalleau et al., 2010; Wabnitz et al., 2010). Geomorphology can be categorized to reflect reef genetic processes at geological scales (Stoddart, 1978; Hopley, 1982; Kennedy and Woodroffe, 2002). Typology of sediment deposits provide information on local catastrophic hydrodynamic processes (Scoffin, 1993). There is virtually an unlimited number of comparative applications for which typologies can be built.

### Geomorphological typology

#### Criteria for a reef typology

In his “Descriptive reef terminology” paper, Stoddart (1978) clearly explains the difficulties in building a useful typology. He focused on geometrical and geological

aspects, but the message is valid for other descriptive and functional levels as well.

Part of the reasons explaining the difficulties in achieving one single typology accepted by all is that most existing typologies are “*derived from imperfect and perhaps biased knowledge of the range and complexity of reef phenomena.*” In other words, historical typologies have been designed using limited numbers of configurations worldwide. They were valid in one context but could not fit easily into another if they were not exhaustive.

Another major issue is that geomorphological classifications have tried to merge two different criteria which are “morphology” and “genesis.” The best example is for the word “Atoll.” Initially an administrative term (*atolu*) in Maldivian language, it was assimilated by first visiting westerners as a generic term to describe annular reef (which are really *faros* in Maldivian). But it was eventually associated with the Darwin (1842) view of the fringing-barrier-atoll genetic sequence that is valid for several Pacific Ocean atolls. Thus, confusion arose on the meaning of the term “Atoll” and how to use it for new areas, as it could characterize shapes and genesis. Shape is easy to characterize, but genesis is not. The paradox is that “Atoll,” considering its theoretical Darwinian meaning,

could not be applied anymore to Maldivian atolls. Another example is the Belizean Lighthouse Atoll, which is structurally similar to the Mexican Chinchoro Bank. Yet, one is named as an “Atoll,” the other as a “Bank.”

To be useful and avoid as much as possible these problems, the terms, classes and labels of a geomorphological typology should be explicit, singular, internally correct, not redundant, innocuous, avoid radical redefinition, and be comparable among different languages (Stoddart, 1978).

### Examples of existing reef typology

The criteria identified above are only partly met by existing typologies and definitions. Among the most structured typology, we can cite the work of Battistini et al. (1975), inspired by Madagascar, Mayotte, New Caledonia, and French Polynesia reefs. Names are provided in French, English, and German. It distinguishes at the top level 14 main classes of formations: fringing reef, boat channel, barrier reef, double or multiple barrier reef, sand cay reef, coral bank, coral head, atoll, almost atoll, faros, emerged reef, drowned reef, lagoon, and coral reef complex. Then, down the hierarchy, it is very detailed regarding fine scale geomorphological features, with

**Reef Typology, Figure 1** Examples of the diversity of Pacific Ocean atoll and island types viewed by Landsat 7 satellite. (a) Agrihan, an island without fringing reef (Northern Marianas Islands); (b) Guam, an island with fringing reef; (c) Maiao, an island with widening fringing reefs and shallow lagoons (French Polynesia); (d) Wallis Island, an island with a deep lagoon and a barrier reef (Wallis and Futuna, France); (e) Wake Island, a shallow lagoon atoll (United States); (f) Haraiki atoll, a deep atoll lagoon with a wide pass and reef islands (French Polynesia); (g) Osprey Reef, a deep atoll without islands, and narrow reef flats (Coral Sea, Australia); (h) Caroline, an atoll with shallow small reticulated basins (Line Island, Kiribati); (i) Kanton, an atoll with deep lagoon and reticulated reefs and rim islands (Phoenix Island, Kiribati); (j) Maria Ouest, a shallow lagoon atoll with islands (French Polynesia); (k) Johnston Atoll, an almost-drowned bank (United States); (l) Ouvea Atoll (right side), a raised atoll with deep lagoon (New Caledonia); (m) Nauru, a raised atoll without lagoon.

**Reef Typology, Figure 2** Main nodes of the Millennium geomorphological typology. The figure shows the three first levels, but two other levels going into greater details of descriptions exist.

14 fore reef (outer slopes) classes, 66 reef flat classes, and 19 lagoonal classes. It exemplified a key aspect of any useful typology. It is hierarchical.

In Battistini et al. (1975), typology and morphologies, and not genesis, are favored to define the broad reef types. Thus, it does not indicate any genetic relationships and processes between structures and can be considered as purely descriptive. Conversely, the fringing reef typology proposed by Kennedy and Woodroffe (2002) is based on the differences of formation of fringing structures. It is based on the internal structure of the reef, and thus can be difficult to diagnose without coring or seismic data. It is based on a limited number of examples.

Based on a larger number of reefs studied with aerial and satellite images, the Great Barrier Reef shelf reef typology proposed by Hopley (1983) is based on the description of the different units that make a reef and its lagoon (coral, rubble, algal pavement, sanded reef flat, detrital slopes and lagoon infill, shingle ramparts, aligned corals, cay, coral pinnacles, submerged reef or lagoon, and Pre-Holocene reefal limestone). The different reef types are linked by possible genetic processes. The diversity of forms and patterns reveal an evolutionary scheme relating one type to another, in terms of growth potential relative to sea level and size of antecedent platform for instance. The classification has thus two criteria: diameter of antecedent platform, and position relative to present sea level (and thus main direction of growth, lateral or vertical).

Another interesting typology made to account for genetic and dynamic processes is the typology of island-atoll proposed by Scott and Rotondo (1983). This study addressed another scale of evolution patterns compared to Hopley (1982) or Kennedy and Woodroffe (2002), since the objects of interest are entire atolls and islands (as raised atolls) of the Pacific Ocean. Scott and Rotondo's (1983) typology extends the Wiens (1962) descriptions with 11 types: volcanic island without reef, volcanic island with fringing reef, raised volcanic island with fringing reef, almost-atoll, raised almost-atoll, atoll, inundated atoll, part raised atoll with open lagoon, part raised atoll with enclosed lagoon, raised atoll with dried out lagoon, and raised atoll with typical form lost. Lithospheric processes (volcanic activity, plate movements, cooling, reheating, and compression) explain the different types of formations found in the Pacific (Allain et al., 2008). Although new information on Pacific bathymetry, seamount locations, and tectonic processes has come to light, the model describes the complexity of physical processes that can alter the different reef and island/atoll forms to provide the variety that we observe for instance in remote sensing images (Figure 1).

Hopley (1982) used aerial photographs and ERTS spaceborne imagery to refine his typology of Great Barrier Reef shelf reefs. Similar tools have been recently used to propose a hierarchical geomorphological typology for all reefs worldwide (Andréfouët et al., 2006). This "Millennium" typology (as coming from the Millennium Coral Reef Mapping Project) is a 5-level hierarchical typology

that provides a total of 800 classes that can be mapped using Landsat 30 m resolution satellite images. This high number reflects the diversity of configurations encountered worldwide and not the diversity found on any particular reef. For a given reef, between one (for a simple apron fringing reef) and 25 classes (for a complex Maldivian atoll) are frequently encountered. The main nodes of the typology are provided in Figure 2. It was designed with Stoddart's (1978) principles in mind, and tried to reconcile several local typologies while taking advantage of a global coverage of Landsat images. The typology and the maps were designed to be helpful for a wide diversity of applications including geology, fisheries, conservation, hydrology, and climate control of reef growth (Andréfouët et al., 2006). A number of coral reef atlases have been produced with this typology (e.g., for all the French overseas reefs in the Atlantic–Caribbean Ocean, Indian Ocean, and Pacific Ocean, see Andréfouët et al., 2008).

### Future typologies

The Millennium typology is the first detailed typology that was built according to the full *range and complexity of reef phenomena* (Stoddart, 1978), at least those that result in patterns visible on Landsat images. It remains descriptive, based on reef configurations and forms, although there is now evidence that the mapped products can be related to reef genesis (Andréfouët et al., 2009). Improvements will come by the validation of the map products and their interpretation using geological data.

Geology is only one aspect of reef processes. Other critical ecological and biological functions are controlled by hydrodynamics and reef complex geometrical spatial properties (e.g., reef fragmentation and larval dispersal). Therefore, it is expected that new regional typologies will be developed to account for reef geomorphology, reef geometrical properties (topology), and hydrodynamics.

Since the year 2000, old and new concepts for building habitats and ecosystem classifications have been revisited in order to help the difficult task of large-scale management of marine ecosystems (Costello, 2009). Biodiversity conservation will certainly be the main driver in establishing relevant typologies in the future.

## REEFAL MICROBIAL CRUSTS

Robert Riding  
University of Tennessee, Knoxville, TN, USA

### Introduction

Fine-grained, non-skeletal crusts, variously described as laminar micrite crusts, cements, stromatolites, and microbialites, are locally common in late Quaternary coral reefs. They occur on wave-swept margins in dark or low-light habitats, such as cavities and deep fore-reef slope surfaces. They have often been regarded as cements, but are now widely interpreted as microbial carbonates produced by heterotrophic bacterial communities. The crusts typically form at the end of active reef development, as late stage veneers on framework skeletons. They can be up to 20 cm thick, and locally constitute 80% of the reef structure. Crusts are particularly important in strengthening cavernous reef frameworks. Their development in poorly illuminated cavity and deepwater habitats suggests eukaryote competition for substrates. Their preferential development at wave-swept reef margins probably indicates the effect of increased carbonate saturation state by intense seawater flushing. Reefal microbial crusts appear to be more common in Late Pleistocene and Early Holocene reefs than in those of the past 6,000 years. Similar crusts are also present in much older reefs. Many questions remain concerning the factors that have controlled their formation and uneven distributions in space and time.

### Recognition

In important papers, Ian Macintyre (e.g., Macintyre, 1977, 1984) drew attention to fine-grained crusts in Holocene Caribbean reefs and reef caves. Their non-skeletal fabrics are evidently precipitated, and these examples, together with others in the Great Barrier Reef (Marshall and Davies, 1981), attracted attention as examples of submarine lithification. Outcrops of Late Miocene reefs in the western Mediterranean revealed their variable distribution and local importance. In *Porites* reefs of Messinian (~6 Myr) age in southern Spain, crust volume can far exceed that of coral. Their clotted-peloidal fabrics can be interpreted as calcified bacterial organic matter, and grains trapped in the crusts on steep or overhanging surfaces suggest adhesive biofilm (Riding et al., 1991). Following recognition of similar features in crusts in cores through late Quaternary reefs at Tahiti (Montaggioni and Camoin, 1993) and in reef caves at St Croix (Zankl, 1993), recognition and interpretation of the crusts as microbial stromatolites and thrombolites became common. They have been particularly well described by Gilbert Camoin and colleagues at Tahiti, where they were among the targets of IODP Expedition 310 in 2005 (Camoin et al., 2007).

### Structure and fabric

Reefal microbial crusts range from millimeters to decimeters in thickness (Figure 1). Their external surfaces can be irregular, smoothly domical, or patterned by 'knobby' dendritic columns (Figure 2). Internally, smooth domes are usually relatively well layered (stromatolitic), whereas the columns are usually more weakly layered.

Crusts exhibit complex internal fine-grained microfabrics, with subordinate allochthonous grains and microencrusting skeletons. Silt-size grains made of fine-grained  $\text{CaCO}_3$  (peloids) are characteristic components of crusts (Macintyre and Marshall, 1988) (Figure 3). These grains, generally <50  $\mu\text{m}$  across, are relatively evenly spaced, and often 'float' in lighter colored microspar that includes irregular sinuous fenestrae up to 250  $\mu\text{m}$  across. Similar aggregates form geopetal fills in small cavities, and it appears that peloids occur both in situ precipitated crusts and as allochthonous (although probably quasi-autochthonous) fills.

### Origin

Even studies that described crusts as cements often invoked bacterial processes, such as decay of organic

**Reefal Microbial Crusts, Figure 1** Fine-grained crusts (light) on dissolved vertical *Porites* branches (dark). Late Messinian (~5.5 Ma), Mesa de Roldán, Almería, SE Spain. The crusts have smooth external surfaces and range in thickness from ~3 mm to 3 cm.

**Reefal Microbial Crusts, Figure 2** Corallgal-microbialite reef framework with ~5 cm of fine-grained crust, showing laminated (L) lower part and dendritic (D) upper part. The crust overlies coralline algae (white) and other skeletal encrusters, which in turn overlie *Acropora* (bottom of picture). Core through late Pleistocene–early Holocene reef, SW Tahiti, IODP 310, Maraa eastern transect, Hole M0015B, Last Deglacial Sequence, Subunit 1B, interval 310-M0015B-19R-01, 59–67 cm (Camoin et al., 2007, p. 4, Figure F16). matter, to account for their formation (Macintyre, 1984, p. 232; Macintyre and Marshall, 1988). Chafetz (1986) proposed that peloids could form in semi-isolated cavities in present-day reefs by bacterially induced precipitation around suspended bacterial colonies. The presence of similar peloids, together with other microfabric comparisons (Riding et al., 1991; Montaggioni and Camoin, 1993; Zankl, 1993), and also the local presence of microbial filaments have all been used to infer a bacterial origin for the crusts. More specifically, their typically magnesian calcite composition, stable isotope values, and biomarkers provide evidence for sulfate-reduction: (a) Reefal peloidal crusts are typically magnesian calcites in the range 12–18 mole% Mg. Difficulties in obtaining such high Mg-calcite compositions inorganically suggest biological involvement such as

**Reefal Microbial Crusts, Figure 3** Peloid microspar microfabric, showing irregularly amalgamated dark peloidal masses in a light microspar, locally fenestral, matrix. bacterial sulfate reduction (Malone et al., 2001, p. 891, and Figure 10). (b) Bacterial processes, specifically sulfate reduction, have been inferred from carbon and oxygen isotope values of peloidal crusts and fills (Land and Goreau, 1970; Pigott and Land, 1986, Figures 9–11; Reitner et al., 2000, p. 153). (c) Reitner et al. (2000, pp. 158–159) found biomarker evidence for anaerobic heterotrophs in Lizard Island and St Croix peloidal crusts. In Tahiti reef crusts, Camoin et al. (1999, p. 297) found muramic and diaminopimelic acid, characteristic of bacterial cell walls, and Heindel et al. (2009) found fatty acids typical of sulfate reducers.

### Living examples

Living microbialites in reef caves are potential analogues for older crusts. Examples are centimetric crusts at Lizard Island and St Croix. These are forming in association with invertebrate and algal encrusters. Their surface microbial mucus can trap sediment and provide a medium for peloid precipitation (Reitner et al., 2000, pp. 154, 156). Chafetz's (1986) proposal that cavity peloids can be calcified bacterial aggregates is supported by the observation of organic remains in the cores of peloids forming in 'degraded microbial organic substances' within microbial films in St Croix caves (Reitner et al., 2000, p. 156, and Figure 5). Raised alkalinity in organic matrices associated with calcification in decaying sponges is 'believed to be largely a result of heavy sulfate reduction' (Reitner et al., 2000, p. 153).

### Sedimentological role

Thick crusts strengthen reef skeletons and reduce cavity volume, especially in branching or platy frameworks. In Messinian reefs of SE Spain, crusts up to 15 cm thick coat vertical *Porites* branches that are 1–3 cm wide and are linked horizontally by thinner platelike connections.

The crusts are therefore often thicker than the corals and locally constitute 80% of the reef volume. Crusts fused the otherwise delicate coral frame into a solid mass while the reef was still forming. The crust-welded reef rock occurs as cuboidal blocks up to 5 m across on the fore-reef slope (Riding et al., 1991). Crusts up to 20 cm thick occur in Late Pleistocene reefs in Tahiti (Camoin et al., 1999).

### Distribution and controls

Crusts occur on wave-swept reef margins in enclosed framework cavities and on deep fore-reef slope surfaces. This is well documented from studies of Late Pleistocene–Holocene reefs (Macintyre, 1977, p. 513; Camoin and Montaggioni, 1994). Their formation in the closing stage of framework growth is reflected by their position between sciaphilic encrusters (e.g., corallines, foraminifers) and overlying reef or pelagic sediment. As light diminishes, reef surfaces are colonized by a succession of increasingly sciaphilic (shade-loving) skeletal organisms: coralline algae, bryozoans, sclerospores, foraminifers, and serpulids. The corallines can include shallower and deeper water communities (Braga et al., 2005; Webster et al., 2009, Figure 8). Fine-grained crusts typically overlie this sequence (Montaggioni and Camoin, 1993) (Figure 4). Crusts are preferentially developed on wave-swept margins, relative to lagoon and platform interior sediments, both in shallow reef crest zones (e.g., Macintyre, 1977) and on deeper foreslopes.

Ability to grow in dark environments is consistent with interpretation of the crusts as products of essentially heterotrophic bacterial communities. It also suggests contest for substrate in which crusts were outcompeted by eukaryote skeletal encrusts (see Eukaryote competition). Preference for wave-swept reef margins suggests the effect of seawater flushing on precipitation. This too is not inconsistent with a microbial origin for reefal crusts since bacterial calcification is strongly dependent on environmental factors that promote precipitation.

Late Quaternary crusts were common during deglacial sea level rise but declined ~6,000 years ago. This secular pattern of late Holocene decline was recognized in Tahiti and other Pacific reefs. A possible explanation is that crust formation was promoted by increases in alkalinity and nutrients in reef waters due to enhanced oceanic upwelling and terrestrial runoff during deglacial sea-level rise, and that these effects declined as sea level stabilized in the mid- Holocene (Camoin et al., 1999, p. 300).

### Eukaryote competition

The restriction of crusts to cryptic environments and deep foreslope habitats suggests competition for space with photophilic eukaryote reef builders. Such competition has long been considered a key factor in the geological decline of stromatolites in marine environments. Applying this view to reefal microbial crusts suggests that they were outcompeted for substrate by algal and invertebrate

**Reefal Microbial Crusts, Figure 4** Succession from coral to fine-grained crust: coral, coralline algae, foraminifers, crust. Variations are common; omitting some components and including additional skeletal encrusters. Based on Figure 2, and Riding et al. (1991, Figure 15), Riding and Tomás (2006, Figure 5), and Webster et al. (2009, Figure 8).

encrusters such as corallines and foraminifers. Only as decreasing illumination excluded even these shade-loving competitors did microbial crusts develop extensively. Relegation to dark habitats thus helps to account for crust development at the end of reef-growth. It also indicates independence of illumination, supporting an essentially heterotrophic interpretation of microbial crust communities.

### Fore-slope drowning

The formation of crusts in deepening sequences at the end of reef growth has been emphasized in studies of deep and drowned late Quaternary reefs. Late Pleistocene–Holocene crusts occur on reef foreslopes at depths of ~80–200 m in widespread locations, e.g., Jamaica, Belize, the Red Sea, Huon Gulf, Papua New Guinea, Tahiti and the Marquesas Islands, and Hawaii (Webster et al., 2009). It is not known whether these deposits are still forming. Presumably, they began to form during deglacial sea-level rise and are now at much greater depths than when they started. These deep ‘slope microbialites’ occupy a position between low-light framework encrusters, such as deep water corallines, and overlying pelagic sediments. Camoin et al. (2006, p. 289) suggested that crusts at Tahiti and the Marquesas Islands formed below 100 m because they overlie deep water assemblages of corallines and foraminifers, are partly contemporaneous with phosphate–FeMg crusts, and are overlain by planktic carbonates. Fore-slope crusts have therefore been regarded as signatures of sea-level rise (Camoin et al., 2006) and, in some cases, of reef drowning (Webster et al., 2009). The drowned reef at ~150 m around Hawaii shows shallow-water *Porites* overlain by sciaphilic skeletal encrusters, followed by microbial crusts (Webster et al., 2009, Figures 6, 8). The microbial crust is estimated to have formed at depths of ~120–150 m or more (Webster et al., 2009, 136–137). The sea-level rise that terminated reef development at this location can be connected to a deglacial meltwater pulse ~14,700 years ago (Webster et al., 2009, Figures 10, 11).

### Older examples

Fine-grained clotted-peloidal crusts are not restricted to geologically young reef corals. Similar examples have been widely recognized in skeletal reefs throughout the Palaeozoic and Mesozoic. Present-day reefal crusts can therefore shed light on the origin and development of much older examples. Early Cretaceous (120 million year) peloidal crusts on scleractinian corals have been interpreted as heterotrophic bacterial carbonates (Riding and Tomás, 2006).

Stromatolites and scleractinian corals can in several respects be regarded as end members of reef construction (Riding et al., 1991). Their locally intimate association in the Quaternary has implications for reef development and environmental change during this interval. The distribution of reefal microbial crusts in space and time, and the factors that have determined their development, are

significant research questions. Living examples need to be related in detail to Quaternary examples, and also to much older ones in the geological record.

### Acknowledgments

I am grateful to Juan Carlos Braga and Jody Webster for advice on the manuscript.

### Definition

A coral reef involves frame-building and frame-binding organisms, unconsolidated sediment fill, and the living veneer, which is an expression of the interactions between environmental and organic activities. Under normal conditions of stable sea level, the reef reflects a balance between the forces of construction (organic growth) and the forces of destruction (erosion, dispersal by transportation, and deposition).

Sediment production processes involve the mechanical and biological erosion of the cemented reef material and the decay/disintegration of the biogenic organisms in which the form of the skeletal material can be either segmented (*Halimeda*), tabular (red algae), or spicular (gorgonians, sponges, and holothurians), and the direct postmortem contribution of primary grains including whole tests of organisms such as foraminifera, small mollusks, and planktic calcareous or siliceous organisms, and the chemical and biochemical precipitation of discrete carbonate particles and cement.

The agents/controls are physical (waves) and currents, abrasion during transport, or biological such as rasping or burrowing organisms. Also, the decomposition of organic tissue may be assisted by bacteria and fungi. In several instances, growth characteristics dictate the skeletal particle size, e.g., benthic foraminifera. Population productivity may determine the initial distribution of the skeletal detritus, e.g., benthic foraminifera, coral, diurnal cycles in pH, dissolved CO<sub>2</sub>, and carbonate saturation may result in precipitation of calcium carbonate either as aragonite, high Mg-calcite, or calcite.

The result of the sediment production either remains in situ or undergoes transportation across the reef top to

the site of deposition. Large coral heads descend down the seaward slope or are thrown up onto the reef rim or reef flat. Coarse rubbles form prominent boulder zones, or coral sticks form conspicuous shingle ridges. Flat *Halimeda* plates form gravel deposits and benthic foraminifera concentrate in ponds or hollows. The sand-sized skeletal fragments are removed from the source area by currents of removal and are transported as bed load to be deposited in the sand wedge adjacent to the lagoon, and the finer sand and silt-sized material is transported in suspension to finally be deposited in the lagoon or carried to the leeward reef slope.

The processes of sediment breakdown can be differentiated into biological (disintegration), physical (attrition which is mechanical and disintegration through impact), mechanical breakdown into individual skeletal microarchitecture, or chemical/biochemical corrosion/solution and bacterial action. The agents/controls are the various organisms such as bottom feeders (sediment ingesters), rasps, grazers, crushers, and borers. The skeletal material thus produced is subjected to the variable energy experienced in the environment related to the strength and frequency of the waves and currents. In addition, the type, size, density, abundance of particles, and the mode of transportation (traction, saltation, and suspension) and the microarchitectural control further influence the relative abundance of particular particle sizes (Stoddart, 1969).

There is a continuous reduction of particle size. Discrete grain-size populations are produced either as skeletal modes or by discontinuous breakdown of the skeletal materials. There is greater fragmentation taking place in the traction load than in suspension. Also, there may be some degree of corrosion of the skeletal particles during passage through the gut of various organisms. In the high energy environments of the Great Barrier Reef, it is rare for fecal pellets to remain intact, and the finer-sized material within the pellets is dispersed by the currents and wave activity. Discontinuous size reduction of the skeletal material will finally produce very fine-grained sedimentary material, which takes the form of carbonate mud (finer than 0.03 mm). These muddy facies are restricted to the central part of the lagoons on the platform reefs, or the sediment wedge to leeward of the reef top.

The processes of transport are either biological (e.g., grazing by fish and turtles) or physical, which involves a winnowing process whereby sedimentary particles are moved in response to the normal physical transportation processes. In addition, very high energy but low frequency cyclonic activity provides an overprinting of the low energy, high frequency transitory waves and tidal currents. The sediments may be differentiated on the basis of particle size, shape, surface texture, and bulk density, and the interrelationship between roughness, threshold velocity, and settling velocity influences the relative importance of different transportation modes.

The effect/product of sediment transportation processes is that lag deposits remain in the high energy zone

near to their source. There is a gradual decrease in the grain size with increasing distance of transport. Eventually, there may be mixing of sediment from multiple sources and different energy regimes. The significance of textural variability is much more difficult to interpret than normal siliciclastic sediments and measurements such as particle size, skewness, standard deviation, and kurtosis that are complicated by the presence of distinct skeletal modes. Deposition is facilitated by the decrease in the velocity of the transporting current or by the influence of organic baffles such as sea grass or *Halimeda*. Some fine-grained sediment particles may be bound together by algal mats.

### Sediments of the Great Barrier Reef, Australia

Detailed studies of sediments from the reef tops of the Great Barrier Reef have been carried out by Maxwell and Swinchatt (1970), Maxwell (1973), Maxwell et al. (1961, 1964), Jell et al. (1965), Orme et al. (1974), Flood and Orme (1977), Jell and Flood (1978), Flood and Scoffin (1978), McLean and Stoddart (1978), Davies and West (1981), Smith et al. (1998), and Frank (2008).

The sedimentary facies may be differentiated on the basis of skeletal components or on the basis of their grain-size composition. There is a general correspondence between the distribution of the sedimentary facies and the morphological and the biological zonation. The reef rim, reef flat, sand wedge, and lagoon sediments display very distinct characteristics of both skeletal components and textural properties. Compositional variations are related to the different contributions of coral, coralline algae, benthic foraminifera, *Halimeda*, and mollusks. Five sediment compositional types have been recognized (Orme and Flood, 1980). Type 1 is high in corals and benthic foraminifera and it occurs at the outer margin windward reef flat and reef rim. Type 2 is high in coral content and occurs along the coral shingle ramparts and reef rim and toward the leeward part of the reef flat. Type 3 has a high percentage of coral and *Halimeda* and it is restricted to the more protected areas of the reef flat. Type 4 facies exhibit a high percentage of benthic foraminifera and it is located in hollows of the seaward extremities of the reef flat and reef rim. Type 5 facies contain a high percentage of *Halimeda* and it is restricted to the more protective part of the reef top such as in the lee of mangroves on the Low Wooded Island reef type.

Flood and Orme (1977) have explained how the general characteristics of the compositional sedimentary facies are related to the stage of morphological/evolutionary development of the reef type (see *Reef Classification by Maxwell (1968)*). The change in compositional sedimentary facies is related to the gradual replacement of reef building framework organisms by the surficial reef top epiphytic organisms such as the benthic foraminifera and plates which grow in the protected environments behind the mangrove vegetation.

There are four major textural types (Orme and Flood, 1980). Type 1 sediments are very coarse sands and gravels, moderate to poorly sorted, and consist predominately of coral and coralline algae. These sediments occur toward the outer windward margin of the reef flat and reef rim. They usually represent lag deposits remaining after wave and tidal action has removed the finer sedimentary particles. Type II sediments are very coarse or coarse sands, moderately well sorted, and consisting predominately of benthic foraminifera with a minor contributions or corals, coralline algae, and *Halimeda*. These sediments occur on the reef rim and the reef flat. Type III sediments are medium to fine sands, moderate to poorly sorted, and consisting of varying proportions of different organisms skeletal fragments. These sediments occur toward the leeward reef zone where sediment is reworked by tidal currents or in subtidal sediment bodies such as the sand wedge transitional between the reef top and the lagoon. Type IV sediments are very fine sands, moderately to poorly sorted, consisting predominately of very fine sand-sized coral fragments and other carbonate mid-sized material. These sediments occur mainly in lagoons on the lagoonal platform reefs where the lagoon acts as a sediment sink. On the platform reefs, this sediment type is transported from the reef top to the sediment wedge leeward of the reef top. The sedimentary texture of this type is principally related to deposition from suspension. These sediments commonly exhibit bimodal or multimodal size distributions that are a manifestation of varying high energy cyclonic events. Type I, II, and III sedimentary facies are transported principally by traction and saltation processes, whereas Type IV sedimentary facies are transported principally in suspension prior to settling. The average size where suspension is the main transportation mechanism is 0.125 mm; the average size where saltation replaces traction processes is 0.5 mm. The overall grain-size distribution is a reflection of the decrease in the energy available to transport sediment across the reef top.

A complex relationship exists between the biological components and the grain size Braithwaite (1973) and is produced by the irregular nature of the breakdown or disintegration of the individual skeletons (Sorby Principle). The following skeletal nodes have been identified within the sand sizes:

Coral (1.68–1.19 mm) and (0.105–0.062 mm),  
Foraminifera (1–0.59 mm larger species) and (0.149–0.125 mm, smaller species),  
Coralline algae (2–1.19 mm),  
*Halimeda* (1–0.125 mm),  
Mollusks (1.68–1.19 and 0.2 mm).

The analyses of the reef top sediments of the Great Barrier Reef show that sediments reflect the varying proportions of the skeletal elements present on the reef and that there exists a textural grain-size gradient from the windward reef margin to the leeward side. This gradient is a reflection of the diminishing wave energy available

for transportation of the skeletal particles. Sometimes, the lagoonal sediments appear to consist of discrete size modes that possibly reflect the rarer higher energy events (e.g., cyclones) more so than the various skeletal modes. Overall, the geomorphical/ecological zonation (reef rim, coral zone, cay, prograding sediment wedge, sediment blanket, shallow lagoon, deep lagoon, and windward vs. leeward reef flat) is reflected in the type of sediment, especially the textural type, more so than the skeletal compositional type. The differentiation of the textural type is a consequence of the environmental energy which influences erosion, transportation, and deposition.

### Sediments of Florida Reefs and Bahamian Reef

Ginsburg (1956) has described the environmental relationship of grain size and constituent particles in some south Florida carbonate sediments. He showed that the grain size and constituent particles reflect the submarine topography and hydrodynamics. Within the reef tract, the skeletal particle sediment constituents coarser than 1/8 mm are *Halimeda*, coralline algae, coral, foraminifera, and mollusks are the dominant skeletal organisms together with varying amounts of fine-grained carbonate sediment (very fine sand and mud-sized material).

Within the reef tract, the depositional environments are reflected in the particle size and constituent particles of their respective sediments.

### Sediments of the Belize Reefs

Macintyre et al. (1987) have described the Barrier Reef sediment apron of Tobacco Reef, Belize. In this reef setting, they have described distinct biological/sedimentological zones that parallel the reef structure. Their study showed that the sediments are transported from the reef crest and fore reef during periods of storms or hurricanes. The particle size of the sediments is largely a result of the differential transport by high bottom-water velocities during the high energy events. There is a positive correlation between the particle size and the distance of the sediment with respect to the reef tract. They recognized five distinct biological zones that paralleled the reef morphology and the back reef apron. They also report the occurrence of Mg-calcite precipitation in the reef lagoon (Macintyre and Aronson, 2006).

### Summary

The processes, agents/controls, and products of sediments of coral reefs have been summarized by Orme (1977). Whether it is the Great Barrier Reef, the Belize Reef, the Florida Reef, the Bahamas Reef, the mid-ocean atolls, the fringing reefs of New Caledonia, Indonesia, Hawaii, and so on, the same patterns of sediment production, sediment transportation, and sediment deposition apply (see Gishler, 1994; Gishler and Hudson, 2004). Irrespective of the different reef organisms that contribute to the source of the sediments, namely coral, coralline algae, *Halimeda*,

foraminiferans, mollusks, etc., the textural types of sediments are very similar in the reef slope, reef crest, reef flat, sand blanket, sand wedge, lagoon, or back reef of the different reef provinces. This reflects the similarity of the physical processes operating in the different environments and the different energy regimes which characterize the environments (Clack and Mountjoy, 1977; Stoddart, 1969).

The presence or absence of aragonite and/or Mg-calcite precipitates is a more vexing issue. Inorganic precipitation has not been conclusively demonstrated in the Great Barrier Reef, but it has been reported in the Belize Barrier Reef lagoon. In the instances where muds have been reported, their origin remains equivocal (Bathurst, 1975). The same can be said for the origins of "whittings," the possible spontaneous precipitates of aragonite, reported from the Bahamas and Persian Gulf. This issue requires further investigation.

## REEFS AT RISK: MAP-BASED ANALYSES OF THREATS TO CORAL REEFS

Lauretta Burke  
 World Resources Institute, Washington, DC, USA

## Definition

*Reefs at Risk* is a series of publications, produced by the World Resources Institute (WRI) in collaboration with partner organizations, that provides detailed spatial analyses of threats to the world's coral reefs.

*Reefs at Risk: A Map-Based Indicator of Threats to the World's Coral Reefs* (Bryant et al., 1998) was the first global, quantitative assessment of threats to coral reefs

ever conducted. Released in 1998, *Reefs at Risk* confirmed that coral reefs are seriously threatened in most parts of the world, clearly identified the human activities which threaten reefs, and called for global action. Over the last decade, the *Reefs at Risk* series – including regional analyses for Southeast Asia (Burke et al., 2002) and the Caribbean (Burke and Maidens, 2004), and local analyses for Sabah, Malaysia (Burke, 2003), and Belize (Burke and Maidens, 2005) – has stimulated public awareness, policy development, and scientific discourse. The series has been useful for conservation priority setting, and has shown decision-makers, politicians and the public where energy and resources should be focused to reduce critical threats.

The *Reefs at Risk* project series is led by WRI, but relies on a partnership with governmental and non-governmental organizations around the world. Partners are vital sources of data, provide guidance on the modeling methods, review model results, and contribute to the final report.

The core of a *Reefs at Risk* analysis is spatial modeling of human pressure on coral reefs within a geographic information system (GIS) framework. Indicators reflecting pressure on coral reefs from coastal development, watershed-based sediment and pollution, marine-based threats, overfishing, and destructive fishing are integrated into the *Reefs at Risk* threat index. Figure 1 provides an example of the typical representations of the integrated threat and level and source of pressures that underlie it.

The original global analysis, *Reefs at Risk: A Map-Based Indicator of the World's Coral Reefs*, uses a 4 km resolution coral reef data set. The regional analyses, *Reefs at Risk in Southeast Asia* and *Reefs at Risk in the Caribbean*, produced results at 1 km resolution. All project results (PDFs of reports and GIS data) can be downloaded from [www.wri.org/reefsatrisk](http://www.wri.org/reefsatrisk) or can be viewed in an interactive GIS at [www.reefbase.org](http://www.reefbase.org).

A new global analysis, *Reefs at Risk Revisited*, was initiated in 2008 and has a planned release in the fall of 2010. The analysis uses higher resolution data than the previous *Reefs at Risk* analyses, with coral reefs at 500 m resolution. It will also consider climate-related threats such as warming and acidifying seas, which were not included in the prior *Reefs at Risk* analyses. Project results will be available at [www.wri.org/reefsatrisk](http://www.wri.org/reefsatrisk) and [www.reefbase.org](http://www.reefbase.org), and data will also be available for viewing in Google Earth.

## REMOTE SENSING

---

Serge Andréfouët  
 Institut de Recherche pour le Développement, Anse Vata,  
 Noumea, New Caledonia

### Definition

Remote sensing is the collection of data without coming into physical contact with the target. In the field of earth, atmosphere and ocean observation, remote sensing generally refers to the use of imaging sensor technologies by ways of aircraft, satellites, ships, and buoys. The target information is carried to a sensor by the electromagnetic radiation or by acoustic sound waves.

### Introduction

Coral reef structures and processes span a large range of spatial scales, from microscale to planetary scale. Smallest scales can be observed in vitro in laboratory and aquaria and in situ. Instruments (such as microscopes, probes, lasers, x-rays, cameras, coring devices, and many others) and visual observations are used in reef geology, physiology, biology, and ecology to elucidate the processes regulating the life of coral reef organisms and the formations of coral reefs. However, above the scale of few tens of meters, it is impossible to measure directly and completely a phenomenon with these techniques. It becomes necessary to sample throughout the spatial domain to acquire representative observations and rely on statistics to estimate means, standard deviations, and probabilities. Often, laboratory and in situ observations cannot be repeated frequently due to costs and logistical limitations to access field sites.

Remote sensing provides the means to make measurements synoptically on reefs, at large spatial scale. This macroscope can be used to scale up field observations. Remote sensing often offers repeatedly acquired data, spanning several decades in some cases. This now provides the most objective basis to assess anthropogenic and climate change effects on a variety of ecosystems. However, there are many technological and

environmental limitations in the type of observations that can be acquired remotely.

Two domains characterize reef remote sensing: the sensing of the reef itself, with its submerged living communities and its carbonate framework and the sensing of the reef physical, chemical, and biological boundary conditions made by the ocean, the atmosphere, and the land masses. Sensus Andréfouët and Riegl (2004), reef sensing and reef environment sensing are respectively direct and indirect reef remote sensing. These approaches have different spatial and temporal focus. They use different types of sensors and technologies adapted to different parts of the electromagnetic and acoustic spectrum.

### Electromagnetic and acoustic spectrum

Radiation across the entire electromagnetic spectrum can be used in remote sensing technologies with increasing wavelength and these are the ultra-violet (0.3–0.4 micrometers [ $\mu\text{m}$ ]), the visible (from blue to red light, 0.4–0.7  $\mu\text{m}$ ), the infrared (0.7–3  $\mu\text{m}$ ), the thermal infrared (3–15  $\mu\text{m}$ ), the far infrared (15–1,000  $\mu\text{m}$ ), and the microwave radiation (above 1,000  $\mu\text{m}$  or in the more common frequency unit used for microwave radiation, 1 giga Hertz [GHz]). Acoustic in-water systems operate at a much lower frequency, between 10 Hz and 1 MHz (Rees, 2001).

### Categories of remote sensing systems

A sensor and its deployment platform (which can harbor several sensors) constitute a remote sensing system. The type of radiation used, frequency of acquisition, platform altitude, and orbit (sun-synchronous, polar, geostationary, etc.) define a system. In addition, a remote sensing mission would also comprise parameters such as energy and life expectancy, recording devices, data transfer and ground receiving stations (for satellite sensors), acquisition scheduling, on-board and on-ground calibration systems, and software and data distribution for end users. Missions are too numerous to describe them exhaustively here, and they have a limited lifetime, thus information can become rapidly obsolete. However, some missions have been maintained over several decades by the repetitive launch of a series of satellites carrying sensors with consistent specifications. This is the case of Landsat 4, 5, and 7, SPOT 1-3, and the NOAA-POES (Polar Operational Environmental Satellites) series of satellites that were initiated respectively in 1982, 1986, and 1978. Remote sensing textbooks (Jensen, 2006; Lillesand et al., 2007; Campbell, 2008) and internet resources often provide a listing of ongoing, past, and sometimes future missions ([http://en.wikipedia.org/wiki/List\\_of\\_Earth\\_observation\\_satellites](http://en.wikipedia.org/wiki/List_of_Earth_observation_satellites)). Table 1 refers to the most common systems used for coral reefs.

Missions are generally government endeavors due to their very high planning and operating costs, but some have also been conceived by private commercial companies such as Orbimage, DigitalGlobe, and GeoEye.

**Remote Sensing, Table 1** Overview of most common remote sensing platforms, sensors types, and applications relevant to coral reef science and management

| Platform                                       | Ship     |       |           | Aircraft          |                 | Satellite                       |                             |           |              |       |                              |                                              |

*Note:* *VHR* very high spatial resolution (<10 m); *HR* high spatial resolution (10–30 m); *MR* medium spatial resolution (30–300 m); “n” not possible; “y” routinely possible; “?” the potential is not fully evaluated, p: has been demonstrated in a limited number of cases, thus possible but warrant further investigations. For “Benthic communities,” an order of the number of classes that can be mapped is provided. However, this is highly site dependent and processing dependent and not necessarily just a function of the sensor. “Fine geomorphology” characterizes structural features of few tens of meters, like spur-and-grooves, crests, small patches, reticulated formations, navigation channels. “Coarse geomorphology” characterizes the identification and mapping of hundreds-of-meters-sized structures such as fringing, patch, and barrier reefs. At this scale, shipborne platform is not suitable. “Measuring coral bleaching” consist in evaluating during a bleaching event the portion of the reef, or the portion of the live coral, that is bleached. “Monitoring water quality” using multispectral satellite is possible but with a limited repeat time. *ASCAT* Advanced Scatterometer on board the MetOp-A satellite; *OSTM* Ocean Surface Topography Mission on board the Jason-2 satellite. Other acronyms: see text. Other information are available in Mumby et al. (2004)

This economic sector has proven highly successful since the launch of the first commercial spaceborne sensor (IKONOS) in 1999. Very high resolution commercial remote sensing is also an important contributor to scientific applications (Goward et al., 2003). Acoustic systems are widely operated by private sector companies.

Remote sensing sensors can be classified in several ways. Useful distinctions are between passive and active sensors and between imaging and nonimaging systems.

Passive sensors detect the radiation emitted or reflected by the target, typically the emitted thermal infrared and the reflected sunlight. Typical passive sensors include film photography, charged coupled devices in cameras, and radiometers. Active systems emit radiation to scan the target and measure the signal reflected or backscattered by the target. A third distinction useful in active systems is between ranging and scattering techniques. Ranging focus on the time delay between transmission and reception of the signal, whereas scattering techniques focus on the strength of the return signal, although both time delays and strength can be used by the same system. Typical are laser-based systems (e.g., LIDAR, standing for Light Detection and Ranging) working in the visible part of

the spectrum, and RADAR systems (Radio Detection and Ranging) working with microwave radiation. This includes scatterometers, altimeters, profiling radars, and synthetic aperture radars.

Acoustic active SONAR (Sound Navigation and Ranging) systems use sound wave propagation in the water to sense the bottom and are not limited by depth, except in very shallow waters. Frequencies and sensors are adapted to the depth range of the study area. Side-scan sonars and single-beam and multi-beam echo sounders have been used principally for depth measurements, but they also provide bottom discrimination capabilities, hence several systems are referred to as Acoustic Ground Discrimination Systems (AGDS).

Imaging sensors (active or passive) produce a two-dimensional (2D) array of information by, for instance, using a 2D matrix of individual sensors (such as charge coupled devices or digitized film photography) or by using 1D sensor and the motion of the platform to scan the target. The interest of imaging systems is to produce a swath measurement, a pictorial representation of radiation as a function of position on the target. Imaging systems are used to create maps of the targeted portion of the Earth surface.

**Remote Sensing, Figure 1** Examples for a nearly 1-km-wide flat reef of the information provided by: (left) a high-resolution (20 m), multispectral, spaceborne sensor like SPOT-HRV and (right) a very high spatial resolution (1 m), hyperspectral, airborne sensor like CASI. Hyperspectral data offers the possibility to work with the most useful bands, for instance, to map brown algae biomass on the reef crest (upper rectangle) or a green algal bloom occurring on the fringing reef (lower rectangle).

### Spatial, spectral, and temporal resolutions

From a user standpoint, systems and remote sensing images can be usefully characterized by at least their spatial, spectral, and temporal resolutions. Figure 1 compares, for the same site, images at different spatial and spectral resolution.

A consequence of the field of view of the sensor and its altitude, the spatial resolution, is the size of the area on the target covered by each sampling unit. In other words, it is the size on ground of the pixel (picture element) of the digital image. This is different to the minimum discernible unit (MDU), which is larger than the spatial resolution: a 1-m spatial resolution sensor will not discriminate 1-m-size objects, but at best 2–3 m-size objects. The MDU limit is inherent to the sensor, but also dependent on environmental and geometrical conditions at the time of the acquisition and the type of processing and resampling that is applied to the image, for instance, to correct for geometric distortion.

The spectral resolution is defined by the number and width of the portions of the electromagnetic spectrum measured by the sensor. These so-called spectral bands are defined by their positions (center, width) and by their sensitivity curves. Panchromatic and multispectral sensors dominate passive optical sensors. Respectively, they provide one large and up to four narrow spectral bands in the visible range. Hyperspectral sensors provide up to several tens of nonoverlapping narrow bands in the 0.4–0.7- $\mu\text{m}$  visibility. Unfortunately, they are still limited to few airborne deployments worldwide. In 2010, only one high spatial resolution hyperspectral sensor was launched into space (Hyperion), and one medium spatial resolution (300 m) 15-band sensor (MERIS).

The temporal resolution is the minimum time interval between two acquisitions of the same target. These acquisitions can be real or virtual depending on the mission scheduling of acquisitions. Low resolution sensors such as SeaWiFS or MODIS may acquire data at every opportunity with a revisit time of only 1–2 days, while high-resolution sensors such as Landsat ETM+ or SPOT HRG need to be programmed and data are acquired only on demand. For instance, the Landsat satellite revisit time is 16 days, but images may be acquired only once a year (Arvidson et al., 2001). Geostationary sensors look at their target continually, thus revisit time can be as often as required. Commercial sensor providers have an on-demand strategy, but they have also built systematic quasi-global archives of images which will be extremely useful in the case of detection of change.

### The infrared limit

Radiations at wavelength higher than the infrared cannot penetrate water bodies by much more than 1 m in the best case. Quickly, they provide only surface skin information. Since they also provide information on the atmosphere

above the water, and on the land masses, they can be of use when studying coral reef processes influenced by atmospheric and terrestrial processes and cannot be neglected for indirect reef remote sensing. Much information can also be gained within these wavelengths when applied to exposed reef flats at low tide.

At shorter wavelength than the infrared, incident light can penetrate the water, and an upwelling water-leaving radiance signal coming from the water column can be measured by a surface, airborne or spaceborne, downward-looking sensor. The physical and biological interpretation of this radiance signal requires an understanding of the radiative transfer theory. Radiative transfer characterizes the change in direction and intensity of radiation in the air, in the water, and at their interface, due to inherent (absorption, scattering) and apparent optical properties (reflectances, diffuse attenuations, and inelastic scattering like fluorescence). For optically shallow water of depth  $z$ , the water column and the bottom signal that can be measured at the sensor level depend on the incident light, the water optical properties, the reflective and scattering properties of the bottom, the air–sea interface, and the atmosphere (Mobley, 1994; Kirk, 1994). Maritorena et al. (1994) present in a remote sensing context a useful analytical model for optically shallow water when the bottom contributes to the surface signal. It is much more difficult to characterize water optics and interpret images with radiative transfer equations in shallow coastal environments than in the deep ocean, since products in the water can typically have various origins and nature (phytoplankton, colored dissolved organic matter, particulate organic and inorganic matter).

### Processing

Because remote sensing is based on the characterization of electromagnetic radiation and sound waves, data processing relies on a physics-based approach to identify the target signal among the other environmental signals that can be considered as noise. In principle, physics-based algorithms imply site-independent and globally valid processing methods. Applying radiative transfer equations should, in principle, provide the radiometric (or acoustic if sound wave propagation equations are used) value of the target and thus allow its identification. However, in practice, there are many limits to this approach. First, it is not always feasible to accurately solve radiative transfer equations, because there may be too many unknowns in the equations. A solution would be to deploy in situ instruments to acquire, for instance, in-water optical data at the time of the remote sensing acquisition, but this is often unpractical. The second and most important reason is that a radiometric or acoustic value, even if precisely estimated, does not necessarily have a meaning and an immediate interest in terms of ecological, biological, or geological process. In these thematic domains, empirical statistics are often necessary to

define thematic objects of interest, especially for the large objects that could be identified at a size consistent with the spatial resolution of the sensor (living communities, habitats, carbonate structures). Thus, to make the connection between the information contained on the image pixel and the statistically defined ground information, statistical processing of the images is often enough, without the need to fully characterize the electromagnetic signal. In this processing, the output information is not the absolute precise physical signature of any given pixel, but rather the fact that a cluster of similarly colored pixels are significantly different than another cluster. Statistical processing offers a large panel of image-based techniques based on pixel color and spatial configuration (supervised and unsupervised classification, hard and fuzzy classification, segmentation, texture). It is typically a site-dependent, image-dependent processing. The physics-based and statistics-based approaches have been named “reef-up” and “sensor-down” approaches respectively (*sensu* Hochberg et al., 2003; Purkis, 2005).

Recent method development applied to the direct or indirect reef remote sensing is computational intelligence (Ressom et al., 2005). These mathematical models come from the Artificial Intelligence field to extract knowledge from large data sets, to solve optimization problems, and to transform human expert knowledge into mathematical description and algorithms. It includes, among the most frequently encountered techniques, neural networks, genetic algorithms, and fuzzy logic systems. Present applications are limited to water quality analysis in coastal waters and habitat mapping, but this is likely to increase in the future.

Practically, most modern applications rely on a combination of the physical, statistical, and computational intelligence approaches. Typically, the physics-based processing provides images radiometrically corrected to have consistent radiometric information for multi-images, multi-temporal, and multi-site comparisons. Statistical processing is then used to extract thematically relevant information from the calibrated images. Finally, computational intelligence methods and expert knowledge can be used to refine an analysis, if errors and possible improvements have been detected. This mix of approaches is useful for both direct and indirect remote sensing.

### **Spectral signatures and the hyperspectral potential**

With the emergence of numerous airborne hyperspectral sensors in the early years of the 1990s, marine imaging spectrometry developed quickly, including for shallow waters and coral reefs. Areas covered by airborne hyperspectral surveys in the years 1995–2010 include selected reefs in Mauritius, La Réunion, Turk and Caicos, Florida, Bahamas, French Polynesia, Hawaii, Japan, Virgin

Islands, Puerto Rico, Belize, Australia, Seychelles, and Indonesia. Sensors include, but are not limited to, AVIRIS (Airborne Visible Infrared Imaging Spectrometer), MASTER (MODIS/ASTER Airborne Simulator), CASI (Compact Airborne Spectrographic Imager), AISA (Airborne Imaging Spectoradiometer for Applications), PHILLS (Portable Hyperspectral Imager for Low Light Spectroscopy), and HYMap (Hyperspectral Mapper). Note that one acronym may represent several versions of an instrument, as these high-technology devices are continuously enhanced. Hyperspectral airborne studies have been generally paralleled by the acquisition of spectral signatures on the ground.

Spectrometry focuses on the collection and characterization of continuous spectra acquired in laboratory (reflectance), in situ with portable and sometimes waterproof radiometers (radiance reflectance), and by remote sensing (remote sensing reflectance). Spectra are analyzed in intensities and shapes according to the absorption features partly due to the pigment compounds of the target (Hedley and Mumby, 2002). This target is often made of a mosaic of centimeter-scale “pure” constituents. Representative spectra of these constituents (the so-called end members) form a spectral library that can be used in theory to interpret hyperspectral remote sensing images using radiative transfer equations, in order to create, for instance, a map of living communities for the targeted reef. However, these end members do not necessarily have just one “representative” spectrum (e.g., for corals, see Figure 2 and Hochberg et al., 2004). Furthermore, since similar pigments can be found in a large variety of organisms, discriminant spectra for every biological end member may not exist (e.g., for hard coral, soft coral, fleshy algae, turf algae, colonized rubble, microbial mats [Hochberg et al., 2003]). Finally, on the ground, these end-member spectra merge at the scale of few centimeters given the high patchiness of benthic cover in coral reefs. Effective and routine spatial and spectral unmixing of end-member spectra from image acquisitions remain a future target at this stage. These considerations have complicated the automatic processing of hyperspectral images, even with the most recent and performing optimization techniques (Lee et al., 2001).

In fact, simulations have shown that a multispectral sensor with less than 10 bands with adequate spacing and width would be ideal for reef studies (Hochberg and Atkinson, 2003). Although a number of space missions dedicated to coral reefs have been discussed, none of them was funded beyond preliminary feasibility studies. To date, the only high spatial-resolution missions with a dedicated coral reef acquisition plan are the Landsat 7 mission and the collection of digital photographs taken from the International Space Station by astronauts (Arvidson et al., 2001; Robinson et al., 2006).

Despite confounding signatures and the absence of a nongovernmental very high spatial resolution

**Remote Sensing, Figure 2** Variability in spectral signatures (reflectance  $R$ ) of corals, specifically for *Montastrea annularis* and *Porites sp.* Panels (a) and (c) show mean absolute and normalized  $R$ , respectively, for ten colonies at three sites in the Caribbean. Panels (b) and (d) show mean absolute and normalized  $R$ , respectively, for ten sites around the world (b). (Data from Hochberg et al., 2004.)

hyperspectral spaceborne sensor in 2010, hyperspectral data and spectrometry remain a promising field for coral reef investigations. It is predictable that near-future on-demand availability of affordable hyperspectral data will quickly transform the field of direct coral reef remote sensing.

### Past and current application of optical passive sensors for direct reef remote sensing

For direct remote sensing, down-looking, passive optical remote sensors in air and space provide data in the blue-near infra red part of the spectrum that are useful for coral reef observations. These optical data have vastly dominated, and still dominate, the field of direct coral reef remote sensing. Historically, airborne photography cameras were first used, followed by high-resolution, spaceborne, multispectral sensors (on board the various Landsat, SPOT, IRS spacecrafts) in the 1980–1990s, then

airborne hyperspectral sensors (such as AVIRIS, CASI, AISA, PHILLS) in the 1990s, followed by the emergence of very high resolution, spaceborne, multispectral sensors (on-board IKONOS, Quickbird, FORMOSAT, GEOYE 1, SPOT-5, Orbview-4). Aerial photography and multispectral spaceborne sensors remain the most frequent data source. The very high spatial resolution commercial sensors are increasingly used, given their interesting resolutions compared to other sensors, but they remain often limited to small-scale projects, for a particular site (Mumby and Edwards, 2002; Andréfouët et al., 2003; Capolsini et al., 2003).

Main applications are listed in Table 1. The dominant application is habitat and community mapping (Figure 3), then bathymetry modeling, itself a necessary part of benthic rugosity assessment. These applications still remain actively pursued research and management topics, since the achieved accuracy is not necessarily very high (Mumby

**Remote Sensing, Figure 3** Examples of geomorphology and benthic maps achieved for Wallis Island using digitized aerial photographs. Different types of maps can be produced depending on the applications. All these maps can be considered as habitat maps, displaying different thematic resolution. *Map E* is the most complex, with 56 classes. (Details in Andréfouët, 2008.)

et al., 2004; Knudby et al., 2007; Lyzenga et al., 2006; Andréfouët 2008; Minghelli-Roman et al., 2009). It is predicted that the number of applications involving the detection of changes will grow, often by combining

different image sources, including aerial photographs, to span the longest possible period (Scopélitis et al., 2009). Finally, it must be pointed out that the elaboration of remote sensing products is frequently not anymore the final goal

and focus of the most recent published study (Andréfouët and Riegl, 2004). Publications become much more user oriented than producer oriented. Interdisciplinary studies taking advantage of remote sensing capabilities and products are increasing, for instance, in geology, ecological modeling, monitoring sampling design, biodiversity applications, conservation planning, and fishery management (Gilbert et al., 2006; Pittman et al., 2009; Purkis et al., 2008; Riegl et al., 2007; Green et al., 2009).

### **Past and current application of acoustic and optical active sensors for direct reef remote sensing**

Active in-water acoustic systems operated from small boats are increasingly used, partly because optical data are quickly limited by depth and turbidity and partly because acoustic systems provide precise bathymetric data that can be used to correct optical data for water column attenuation effects. However, acoustic data are useful for their own sake, to measure depth, identify bottom features and map habitats, although they cannot resolve as many habitats as optical data would do. Most common AGDS sensors are RoxAnn<sup>®</sup>, Qeuster Tangent Corp (QTC)-View<sup>®</sup>, and ECHOpus<sup>TM</sup>. A full review of past coral reef applications is provided by Gleason (2009). The predicted trend is to see a better synergy between acoustic and passive optical acquisitions for local scale applications (Riegl and Purkis, 2005).

Although still fairly uncommon due to costs of data acquisition, the active airborne lidar systems have proven their utility (Brock and Purkis, 2009; Costa et al., 2009). Extensive data sets exist in waters under United States jurisdiction (e.g., Hawaii, Florida, Puerto Rico, Virgin Islands) and over the Great Barrier Reef, acquired with SHOALS (Scanning Hydrographic Operational Airborne Lidar Surveys), EAARL (Experimental Advanced Airborne Research Lidar), and LADS (Laser Airborne Depth Sounder) systems. Data collection occurred in 2009 in the Indian Ocean coral reefs under French jurisdiction. Lidar accurately provides bathymetric data that can be acquired, as another major advantage, simultaneously with optical data if a camera or radiometer is on the same platform (Brock et al., 2004). Lidar data have been processed to extract rugosity information, which is a key habitat descriptor, for instance, to explain and predict the distribution of fish communities (Pittman et al., 2009).

Finally, in-water laser-induced fluorescence deployed at night with the FILLS (Fluorescence Imaging Laser Line Scanner) has been successfully tested to map reef communities, at a spatial resolution of a few centimeters. However, this has remained experimental and has not been generalized (Mazel et al., 2003).

Similar to passive optical data, active remote sensing products are now directly used in thematic studies relevant to fishery management, geology, biodiversity, and species–habitat relationships, and marine protected areas (e.g., Kuffner et al., 2007; Gleason, 2009).

### **Past and current application of thermal infrared passive sensors for indirect reef remote sensing**

Thermal infra-red data have been used for indirect remote sensing of reefs since the 1990s, especially using the AVHRR (Advanced Very High Resolution Radiometer) sensors that provide Sea Surface Temperature (SST) (Gleason and Strong, 1995). In the wake of the coral bleaching events related to strong El Niño and positive thermal anomalies in 1998, SST-derived proxies have been much more intensely used to forecast coral bleaching. Warnings are issued by the NOAA Coral Reef Watch project whenever the critical threshold of warming stress is approached. The threshold depends on the stress index used, for instance, the global Degree Heating Weeks (Figure 4). Local indices exist, such as Max3d, which was identified for the Great Barrier Reef (Berkelmans et al., 2004). The validity of these SST-based proxies is under discussion, especially in the light of their coarse spatial resolution (0.5° or roughly 50 km, worldwide), compared to the spatial patchiness at which bleaching occurs. Another discussion topic is the refinement and validation of the issued forecasts using ancillary environmental and biological data (McClanahan et al., 2007; Maina et al., 2008; van Hooidonk and Hubert, 2009). Nevertheless, correlations between thermal stress indices and bleaching observations were high during the 1998 and 2002 largest events on record. Absence of bleaching in areas of observed thermal stress are noteworthy, as they may point to local scale hydrodynamic processes that efficiently mix water masses or to local ecological–biological adaptation to thermal stresses (Schiller et al., 2009).

### **Past and current application of ocean color passive sensors for indirect reef remote sensing**

Since 1978, ocean color sensors, like CZCS (Coastal Zone Coastal Scanner), SeaWiFS (Sea-viewing Wide Field-of-View Sensor, launched by the private company Orbimage), MODIS (Moderate Resolution Imaging Spectroradiometer), and MERIS (Medium Resolution Imaging Spectrometer) are typically multispectral with narrow bands, high sensitivity, and hectometric to kilometric spatial resolution sensors. These sensors were designed to measure chlorophyll concentrations in oceanic waters as a tracer of phytoplankton dynamics and primary productivity (Muller-Karger et al., 2005). The sensor's specifications have greatly improved through time to be able to accurately correct for the dominant atmospheric signal above the deep and dark oceanic waters, to estimate chlorophyll and other pigment concentrations, and to provide a suite of ocean color and atmospheric products for offshore and coastal waters. New missions are planned in the future by several space agencies, including using geostationary platforms (IOCCG, 1998, 1999; McClain, 2009).

Offshore, water color is dominated by phytoplankton and its residue. Along the coast, colored dissolved organic matter (CDOM, also called gelbstoff or yellow substances)

**Remote Sensing, Figure 4** Degree Heating Weeks in the Pacific Ocean in early 2002 at the beginning of a severe bleaching event (see Berkelmans et al., 2004). In the tropics, bleaching risks were detected as very high in eastern Australia, along the Great Barrier Reef. (Data courtesy of [http://coralreefwatch.noaa.gov/satellite/current/products\\_dhw.html](http://coralreefwatch.noaa.gov/satellite/current/products_dhw.html).)

and other inorganic–organic particulate suspended matter add to the complexity of the optical system. Ocean color sensors and processing methods have been primarily designed to monitor the dynamics of chlorophyll in the deep ocean. Coastal waters require specific algorithms accounting for the three components as well as the bottom signals in optically shallow water. These algorithms are now often locally optimized using in situ data and statistical and computer intelligence methods (IOCCG, 2000).

Waters circulating around reefs may import to remote reefs various dissolved and particulate material, from rivers and land. Conversely, reefs export material to the coast, deep ocean areas, and other reefs. Thus, ocean color data have been used to reveal the movement of water (physical connectivity) between land and reefs in the Caribbean and in Australia (Hallock et al., 1993; Gabric et al., 1990; Soto et al., 2009) to estimate the export of sediment after the passage of hurricanes in Bermuda and Cuba (Acker et al., 2004), and the export of CDOM from shallow seagrass-rich Bahamas bank areas to deeper water (Otis et al., 2004). Ocean color data are also used in large coastal systems like the Great Barrier Reef and the Florida Keys to routinely monitor water quality. These products are useful to examine the large-scale mechanisms that affect coral reefs, such as the influence of distant river mouths and their plumes, and algal blooms (Hu et al., 2004).

## Conclusions

Perhaps the main issues in reef remote sensing are related to the dispersal and transmission of knowledge and

expertise, so that images and products can be widely used. Despite the vast potential, and the fact that recent publications present applied remote sensing results set in an interdisciplinary framework, reef remote sensing mostly remains in the scientific and academic realm. It is far from having achieved its full potential for applied science, management, economic development, and capacity building.

Both producers and users need to examine the possibilities. Users should not be overwhelmed by the high-tech image that remote sensing carries and they should not have unrealistic expectations. It is possible to have excellent cost-effective reef-scale map products with simple processing of commercial high-resolution imagery, by favoring statistical and expert-knowledge-based approaches instead of more specialized physics-based approach. To monitor reef environments, managers can easily access indirect remote sensing products on public online servers, avoiding the need to process raw data themselves. On the other hand, remote sensing specialists should also be more attentive to the needs of managers and thematians. They should present to potential users the different panel of options, considering cost-effectiveness and the goals of the applications.

Technically, direct reef remote sensing will reach its full potential when affordable hyperspectral (or optimized multispectral) data is available on demand for any area worldwide, most likely through commercial channels. There is no doubt that hyperspectral images will significantly enhance the accuracy and thematic complexity of reef-scale mapping products. New fields of investigation will be opened. Hyperspectral data are also more suitable to physics-based approaches, and divergences between

different processing schools of thought may disappear. However, the handling and processing of these data may be less easily grasped by managers and nonspecialists. Thus, availability of hyperspectral data may not necessarily imply more products actively used for real-life reef environmental management.

Indirect remote sensing is a major topic, especially considering global climate change and its effects on coral reefs. Combined with modeling tools and computational approaches, it is expected that the indirect remote sensing will develop along three avenues: (1) integration of a wide panel of remotely sensed environmental products in addition to SST, solar insolation, cloud cover, and ocean color products (see Maina et al., 2008). Other applications related to climate change include monitoring swell and wind regime products from microwave scatterometer and altimeter instruments that have been seldom used in a coral reef context. Sea level variation is another key parameter to watch in a changing climate era; (2) multi-source data fusion will be enhanced by the use of in situ data and by the combined use of numerical circulation models, possibly through assimilation; and (3) local optimization will be favored, in order to replace global average products by fine tuned high-resolution (1–4 km) products that monitor the local processes more accurately (Maynard et al., 2008).

## RESIDENCE TIME

Thomas Stieglitz, Peter Ridd  
School of Engineering & Physical Sciences, James Cook  
University, Townsville, QLD, Australia

### Synonyms

Flushing time; Mixing time; Water age

### Definition

The residence time is the characteristic time that a parcel of water will remain within a water body. The quantitative definition of “residence time” varies in the literature (Monsen et al., 2002). Generally, it is implied that a complete exchange of the water does not occur in this time. For this reason, the residence time is sometimes defined as the time for some fraction of the water to be exchanged.

The residence time in a partially enclosed water body varies with oceanographic conditions, such as tides, waves and oceanic currents, and depends on the size of the water body and the degree of hydrodynamic connection with adjacent water bodies. Residence time is one of the key parameters controlling the fate of solutes in an enclosed water body such as a coral reef lagoon. A long residence time could, for example, allow accumulation of pollutants. Residence time can also be very important in the (passive) dispersal of larvae.

The residence time can be calculated by hydrodynamic modeling, using virtual lagrangian drifters. For direct measurement in small systems, a dye can be artificially injected and its movements followed, and in larger systems naturally occurring tracers such as the concentration of salt or radionuclides are used.

Tracer data in the central Great Barrier Reef lagoon indicate typical residence time scales of weeks, ranging between 2.5 and 6.5 weeks from inner to mid shelf and from mid shelf to outer shelf respectively (e.g., Hancock et al., 2006). In contrast, residence times inferred from a numerical model of the same region are around six months (Luick et al., 2007), indicating a need for ongoing research to resolve such discrepancies between measured and modeled results.

On spatial scales of coral atolls or single reefs, residence time can vary widely depending on driving forces from a few hours in a small coral reef to tens of days in larger reefal lagoons (Kraines et al., 1998; Delesalle and Sournia, 1992).

## RETICULATED REEFS

Colin D. Woodroffe  
University of Wollongong, Wollongong, NSW, Australia

### Definition

Reticulated, or reticulate, reefs are networks of linear or polygonal reef framework with intervening depressions (the larger of which are called blue holes), which may occur on fringing reefs, barrier reefs, and atolls.

### Introduction

Networks of linear or polygonal reef framework, forming a honeycomb-like mesh of coral-fringed depressions are known as reticulated or reticulate reefs. They occur on fringing reefs (e.g., Red Sea, Shroeder and Nasr, 1983; Madagascar, Guilcher, 1988), barrier reefs (e.g., New Georgia, Stoddart, 1969; Belize, Purdy, 1974; the Great Barrier Reef, Marshall and Davies, 1982; Hopley et al., 2007; Mayotte, Guilcher, 1988; Society Islands, Guilcher, 1988), and on atolls, where they are so distinctive that Guilcher (1988) recognized “reticulated atolls” as a distinct atoll morphology.

Mataiva, the most northwesterly of all the Tuamotu atolls, is a relatively small atoll (10 km by 5 km), but its lagoon with an area of 25 km<sup>2</sup> comprises a particularly distinctive network of reticulated reefs (Figure 1). The reefs, ranging in width from 30 to 300 m, divide the lagoon waters into a series of shallow depressions (Delesalle, 1985; Adjias et al., 1990). Mataiva has an almost continuous reef island around its perimeter, and small reef islands are also found on the reticulated reefs themselves.

Reticulate reefs are apparent in many atoll lagoons (Shepard, 1970). Kanton, known as Abarringa, the most northerly of the Rawaki Islands in the Phoenix group of central Kiribati also has a prominent reticulated lagoon, as does Fanning Atoll in the Line Islands. Many of the northwestern Hawaiian Islands show a reticulate pattern

**Reticulated Reefs, Figure 1** An oblique aerial view of Mataiva, the northwesternmost of the Tuamotu atolls, which has a particularly well-developed network of reticulated reefs in its lagoon.

of reefs, most prominent on Pearl and Hermes, Lisianski Island, Maro, and French Frigate Shoals (Rooney et al., 2008). Similar reticulate patterns occur in the lagoons of other atolls in both the Pacific Ocean (e.g., Eniwetok and Bikini, Emery et al., 1954; Elizabeth Reef at the southern limit to reef development in the Pacific, Woodroffe et al., 2004) and Indian Ocean (e.g., the Cocos (Keeling) Islands, Woodroffe et al., 1994).

On Christmas Island (Kiritimati), the largest of the atolls in the Line Islands of eastern Kiribati, the reticulate pattern of reefs is largely emergent above sea level. The lagoon has a complex pattern of shallow coral patches and sand bars, and this pattern grades to the east into a barren scrub-covered hardpan covering the island's interior. Within this there is a maze of hypersaline pools separated by emergent fossil reefs of mid-Holocene age (Woodroffe and McLean, 1998).

Reticulated reefs are also found in other reef systems. In the Caribbean, they occur at Alacranes on the Mexican coast and in Golfo de Guacanayabo in Cuba. There are reticulate reefs within the barrier reefs of New Caledonia, such as at Tétambia Reef. They are also apparent on the eastern margin of the reef platforms of the Abrolhos Islands in Western Australia.

### Mode of formation of reticulate reefs

The most widely held view is that reticulated reefs develop through a combination of vertical reef growth, forming the reef framework, and subaerial solution by processes of karstification at times of lower sea level, which

accentuates the depressions between the reefs (Guilcher, 1988). The important role that erosional processes play during times of lower sea level, and the subsequent drowning of this antecedent topography, with reef establishment over the topographic high points has been widely recognized (MacNeil, 1954; Purdy, 1974; Hopley et al., 2007). Mildly acidic rainfall results in gradual dissolution of limestone generating a pitted topography of enclosed depressions bounded by steep margins (Solution processes/Reef erosion). The deeper depressions are called blue holes (*Blue Hole*). This view seems to explain many of the features of reticulated reefs, but is not universally accepted (e.g., Gray, 1991; Purdy and Winterer, 2001).

In the case of Mataiva, the distinct nature of the lagoon has been attributed to an earlier phase of erosion of a dolomitized and phosphatized pre-Pleistocene limestone surface that is exposed around the atoll rim (Delesalle, 1985). Emergence during the mid- or late Holocene has resulted in some of the reticulate reefs of the Mataiva lagoon becoming exposed above sea level which has enabled islands to form on them. The interior of Christmas Island, described above, with its maze of hypersaline lakes appears to represent a further stage in this process of emergence.

An alternative view has been proposed for the origin of the network of blue holes in the Abrolhos Islands by Wyrwoll et al. (2006), based on drilling and dating. Their studies have shown thicknesses of more than 20 m of Holocene reef growth and they view the reef framework as constructional rather than the product of karst erosion at lower sea level.

Extensive karst erosion also seems unlikely in very arid areas, but in many places, such as the Red Sea, there are prominent reticulate reefs. Purkis et al. (2010) have recently suggested that the network of reefs indicates solution of limestone foundations beneath these reefs and is evidence for altered climate in this region over the late Quaternary, particularly a wetter phase a few thousand years ago.

## Summary

Networks of reticulated reefs show similar mesh-like morphology on reefs from around the world. Whereas subaerial karst erosion during times of lower sea level seems to have contributed to the development of most of these patterns, there are situations where other factors may have played a role in their formation. Constructional reef growth is important in their development, isolating the intervening depressions which are then unable to support coral growth.

## RHODOLITHS

Lucien F. Montaggioni  
 University of Provence, Marseille Cedex 3, France

## Synonyms

Red algal nodules (balls or macroids); Rhodoids

## Definition

Rhodoliths are defined as free-living nodules that are dominantly composed of calcifying red algae (mostly corallinaceae, occasionally peyssonneliaceae) commonly associated with other encrusters (foraminifera, bryozoans, bivalves, serpulid worms and/or corals). Their size ranges from less than 30 mm to about 300 mm (Bosellini and Ginsburg, 1971).

*Habitat and biotic composition:* Rhodolith deposits occur worldwide along shelves at euphotic depths (generally less than 150 m). The shape, internal structure, composition and growth rate of rhodoliths vary according to environment, water energy and depth. In reef provinces, the nodules from shallower, high to moderate energy environments (e.g., reef flats, proximal back-reefs and channels) exhibit massive spheroidal to branching ellipsoidal types, made up of mastophoroid (*Hydrolithon*, *Neogoniolithon*) and/or lithophylloid (*Lithophyllum*,

*Dermatolithon*, *Titanoderma*) laminar crusts growing over a core. Locally, at distal backreef to lagoonal settings, rhodoliths can be monospecific resulting from the isotropic accretion of a single thallus. Those from deeper (greater than 10 m) and low-water energy (e.g., fore-reef slopes and terraces) preferentially form massive to branching, ellipsoidal to discoidal growths composed of melobesioids (*Mesophyllum*, *Lithothamnion*) and lithophylloids, together with occasional mastophoroids and sporolithaceans. The accretionary rates of shallow-water nodules range from about 0.15 to up to 2 mm year<sup>-1</sup> (Bosence, 1983) while those of fore-reef zones are substantially lower, from 0.010 to 0.40 mm year<sup>-1</sup> (Reid and Macintyre, 1988).

**Environmental significance:** Spheroidal growths are considered to be maintained by periodic movement by waves and currents; with increasing size, movement becomes less frequent. Ellipsoidal and discoidal still move around. The attributes of rhodoliths are therefore used as paleoenvironmental indicators, although in many cases these are not sufficiently significant in terms of ecological conditions (Reid and Macintyre, 1988).

## RIVER PLUMES AND CORAL REEFS

---

Miles J. Furnas  
Australian Institute of Marine Science, Townsville MC,  
QLD, Australia

## Definitions

River plume: a discrete body of fresh or low-salinity water discharged from a river mouth into coastal waters.  
Coriolis force: the deflecting effect of the earth's rotation on a moving fluid.

## Introduction

A significant proportion of coral reefs are located close to continental or high-island land masses where they are influenced by terrestrial runoff (Furnas, 2003). This runoff may come from larger rivers or small coastal streams which inundate reefs near the stream mouth. The frequency and intensity of runoff affecting reefs depends on local or regional rainfall distributions, intensity, and duration, which determine the volume and timing of runoff. Coral reefs are widely distributed in parts of the world influenced by monsoonal climate regimes, where there is often a pronounced wet season.

Runoff affects coral reefs in a variety of ways. These include the direct osmotic stress of low salinity on corals (van Woesik and Done, 1997), the influence of suspended sediment (blanketing after deposition, shading; Philipp and Fabricius, 2003), nutrient enrichment of coastal waters (Furnas, 2003), and the transport of terrestrial pollutants into coastal ecosystems (Shaw and Mueller, 2005).

While there is much attention given to the negative effects of runoff on corals and coastal reefs, it is important to remember that coastal reefs often develop in locations with persistent or episodic influence by runoff from natural sources. The location and extent of these reefs reflect long-term interactions between reef growth, disturbance, and mortality due to runoff effects. Nutrients and organic matter in runoff support the wider productivity of coastal ecosystems which sustain corals, plants, and animals living in coastal reefs. Modern changes in coastal and nearshore coral reefs influenced by runoff are largely due to changes in the quantity and nature of materials carried in runoff due to human numbers and land use in catchments rather than changes in the volume of freshwater.

## Formation of River Plumes

In many tropical systems, most freshwater runoff occurs during short-lived episodic or seasonal flood events. During floods, freshwater is pushed through the estuary of coastal rivers and streams, and freshwater plumes extend into coastal waters where fresh and salt waters mix. Freshwater (ca. <1 g dissolved salts L<sup>-1</sup>,  $\rho \approx 1.0 \text{ g cm}^{-3}$ ) has a lower specific gravity (density) than saltwater (33–35 g dissolved salts L<sup>-1</sup>,  $\rho \geq 1.02 \text{ g cm}^{-3}$ ) and floats on top of seawater. Mixing between the fresh and salt water is determined by the amount of physical energy in the system (turbulence) and the density difference between the two water types. The surface layer of freshwater in a river plume may range in thickness from many meters to a few centimeters. It is affected by a number of forcing processes, including wind stress, gravity, and the Coriolis force.

Water coming from a river or stream mouth does not spread uniformly across the surface of adjacent coastal

**River Plumes and Coral Reefs, Figure 1** *Top:* Schematic section through a river plume showing the buoyant plume and the wedge of freshwater in relation to normal sea level. *Bottom:* Schematic diagram of the effect of Coriolis force on river plumes in the Northern and Southern Hemisphere.

waters. The discharged water forms a shallow wedge near the stream mouth (Figure 1). As gravity and buoyancy flatten this wedge, the water is accelerated away from the coast. The moving water comes under the influence of the Coriolis force and is deflected to the right (Northern Hemisphere) or left (Southern Hemisphere). In the absence of currents or other stresses, this causes the flowing plume of river water to turn parallel to the coast, forming a coast-hugging buoyancy current (Burrage et al., 2003). The plume then flattens and disperses due to horizontal and vertical turbulence as it moves along the coast. Plumes from small streams may only go a small distance before dispersing. In contrast, plumes formed by larger rivers such as the flooding Burdekin River in the Great Barrier Reef (Figure 2) may extend for > 500 km along the coast (Wolanski and van Senden, 1983; King et al., 2002).

### Materials in River Plumes

Rivers carry a large variety of dissolved and particulate materials into the sea. The most obvious is the suspended sediment. During flood events, in particular, rivers and streams can be highly turbid with suspended loads reaching several grams per liter. Tropical rivers may also

contain substantial amounts of dissolved and particulate organic matter from eroded soils. The dissolved organic matter (DOM) may be highly colored (colored or chromophoric dissolved organic matter – CDOM), which affects the optical properties of river plumes.

Most suspended sediment carried by rivers is deposited close to the river mouth as flow slows and the turbulent energy of the stream dissipates in the ocean. The mixing of fresh and salt waters causes fine sediment particles and organic macromolecules in the river water to aggregate into larger particles or flocs which rapidly sediment from the water column. Reefs located near river or stream mouths can receive significant sediment loads during flood events, with the sediment blanketing reef surfaces and causing reductions in underwater light levels. The formation of coastal boundary currents tends to trap terrestrial materials in the nearshore zone (e.g., Currie and Johns, 1988; Gagan et al., 1987).

Concentrations of individual forms of dissolved matter can exhibit both conservative and nonconservative behavior in river plumes as fresh and seawater mix. Conservative behavior indicates that concentration changes follow a linear relationship with salinity (Figure 3). Dilution is the governing process.

**River Plumes and Coral Reefs, Figure 2** Natural color satellite imagery of river plumes entering the central Great Barrier Reef (17–19°S) following heavy rainfall in adjacent catchments, February 2007. The large plume at the *bottom* is from the Burdekin River. Data source: NASA GSFC. Processed by M. Slivkoff, AIMS.

Nonconservative behavior is characterized by nonlinear relationships between concentration and salinity. It occurs when ions dissociate or desorb from dissolved or particulate matter as fresh and saltwater mix, or are removed due to precipitation, adsorption onto particles, or biological uptake.

Dissolved nutrients ( $\text{NO}_3^-$ ,  $\text{PO}_4^{3-}$ ,  $\text{Si(OH)}_4$ ) typically exhibit conservative behavior in the early phases of river plume development as fresh and seawater mix but before there has been sufficient time for significant phytoplankton growth (e.g., Devlin and Brodie, 2005). Once significant phytoplankton growth gets underway in the plume waters (Furnas, 1989), nutrient concentrations can be rapidly reduced through uptake, and concentrations exhibit nonconservative salinity distributions. Iron ( $\text{Fe}^{2+}$ ) typically exhibits strong nonconservative behavior in river plumes, as ferric iron is highly insoluble in oxic seawater.

Dissolved nutrient concentrations in river waters are typically many times higher than those occurring in coastal coral reef waters (e.g., Devlin and Brodie, 2005). These nutrients frequently lead to the development of phytoplankton blooms in plume waters. Phytoplanktons, in turn, produce much of the organic matter which supports coastal food webs of pelagic and benthic filter feeders accessible to reef organisms. A small portion of the nutrients may be taken up directly by reef algae and stimulate growth on the reef surface. While high nutrient concentrations may be detrimental to corals and other reef organisms, the direct effect of nutrients in river plumes is less pronounced than the effect of the lower salinity in the plume. Exposure times are usually brief. Most river-derived nutrients are delivered to reefs in the form of dissolved and particulate organic matter which has been taken up by phytoplankton and bacteria and cycled through coastal food webs.

Rivers flowing through agricultural lands also transport a range of agricultural chemicals (Shaw and Mueller, 2005). Elevated concentrations of herbicides and pesticides have been measured in river plumes discharged into the Great Barrier Reef, for example (Lewis et al., 2009). Herbicides, in particular, can exert a detrimental effect on corals. Direct effects of agricultural chemicals on reef systems are not well characterized at this time, particularly in synergy with other stresses associated with river plumes (low salinity).

### Summary

Flooding rivers and streams often form buoyant plumes of fresh and low-salinity water in adjacent coastal zones. In the absence of contrary wind stress, the Coriolis force constrains plumes to a coastal band. Corals and coral reefs can grow in runoff-affected coastal areas when the frequency and intensity of disturbance by freshwater and sediments are low enough to allow ongoing (re-) growth after disturbance events. Nutrients in runoff contribute to the overall productivity of the coastal zone, but can stimulate

**River Plumes and Coral Reefs, Figure 3** Top: Schematic depiction of conservative and nonconservative behaviors of dissolved materials in river plumes. Bottom: Relationships between the concentrations of nitrate, phosphate, silicate, and salinity in the plume of the Tully River after cyclone Winifred, February, 1986 (M. Furnas, unpublished data).

phytoplankton blooms or enhanced growth of benthic algae which can compete with corals. Levels of sediment, nutrients, and other pollutants have increased in modern runoff due to more intensive and extensive human land use in catchments, which may be detrimental to corals in coastal systems.

## ROYAL SOCIETY OF LONDON

---

Tom Spencer  
 University of Cambridge, Cambridge, UK

### Definition

The Royal Society of London is a learned society for science, founded in 1660, which serves as the Academy of Sciences of the U.K.; membership (Fellow of the Royal Society) is a great honor. It funds, publishes, and publicizes scientific research and advises the U.K. Government.

### Background and roles

The Royal Society of London for the Improvement of Natural Knowledge, known simply as the Royal Society, or even the Royal, is a learned society for science. Founded in 1660, it is generally considered to be the oldest such society still in existence. A charitable body whose patron is the reigning monarch, it serves as the Academy of Sciences of the United Kingdom (in which role it receives funding from the U.K. Government). Fellowship (FRS), granted for life, is awarded to scientists after their election by existing Fellows, and is considered a great honour. Fellows must be citizens or residents of a member of the Commonwealth of Nations or the

Republic of Ireland, while a smaller number of Foreign Members (ForMemRS) are drawn from other countries. Fellows from coral reef science in the nineteenth and twentieth centuries have included C.R. Darwin (elected FRS 1839), J.B. Jukes (1853), W.J. Sollas (1889), T.W. Edgeworth David (1900), J. Stanley Gardiner (1908), H.B. Guppy (1918), R.B. Seymour Sewell (1934), and C.M. Yonge (1946). J.D. Dana (1884) and Alexander Agassiz (1891) were elected as Foreign Members. Both Darwin and Dana were holders of the Society's oldest medal, the Copley Medal, and Gardiner and Yonge were awarded the Darwin Medal for their coral reef research. The Society provides reports and science policy advice to the U.K. Government (as for example in the 2005 Report on ocean acidification), promotes the public understanding of science, runs programs to encourage international collaboration in research, and publishes a number of serial titles, including the world's longest running scientific journal (continuously since 1665), the *Philosophical Transactions of the Royal Society*. However, its prime role is to support fundamental research, and in that regard the Society has been intimately involved for over 300 years in promoting and financing coral reef research (Yonge, 1980; Fogg, 2001).

### Support of exploration of the reef seas

From the beginning, the Society wished to expand knowledge of the world's oceans, issuing "Directions to seamen bound for far voyages" in the first volume of the *Transactions* with the aim of gathering observations of scientific value. This was a challenge taken up, by example, by Edmond Halley (FRS 1678) in his late seventeenth century observations on trade winds, ocean currents, and geomagnetic variations in the Atlantic Ocean (Cook, 1998) and by William Dampier who dedicated "A new voyage around the world" (1697) to the then President of the Society, Charles Montague, Earl of Halifax (Preston and Preston, 2004). It was the Society's Transit Committee that recommended that the 1769 transit of Venus across the face of the sun (to aid the determination of true distances in the solar system) should be observed from a site in the South Seas, leading directly to Captain James Cook's (FRS and Copley medallist 1776) first voyage (1768–1771) to Tahiti. From Tahiti, the expedition undertook the first mapping of the Great Barrier Reef, including the disastrous encounter with the Reef at what is now Endeavor Reef on June 11, 1769. The collections made by Joseph Banks (FRS 1776; President of the Royal Society 1778–1820) and Daniel Solander (FRS 1764) included corals; these were described in *The natural history of many curious and uncommon zoophytes collected from various parts of the globe*, authored by John Ellis (FRS 1754; Copley medallist 1767 and an early proponent of reef-building corals being animals) and Solander and published in 1786. Cook's second voyage (1772–1775), sponsored by the Society to search for the mythical "Terra Australis", utilized the Larcum Kendall K1 chronometer

(a copy of John Harrison's clock H4), which enabled Cook to calculate his longitudinal position with much greater accuracy and thus marked a step change in the positioning of islands within the reef seas. It was the naturalist Johann Reinhold Forster (FRS 1772) on this voyage who made the fundamental distinction between "high" islands, thought to be the product of earthquakes and volcanic activity, and "low" islands, formed by sinking and coral growth (Hoare, 1982). In the nineteenth century, through its Circumnavigation Committee, the Society obtained the use of *HMS Challenger* from the Royal Navy and in 1872 modified it for scientific work, equipping it with separate laboratories for natural history and chemistry. Under the scientific supervision of Charles Wyville Thomson, the voyage (1873–1876) effectively marked the birth of modern oceanography, covering over 100,000 km and conducting almost 500 deep-sea soundings, over 100 bottom dredges and open water trawls, and over 250 measurements of water temperature; the Expedition Report catalogued over 4,000 previously unknown species (Deacon, 1971). The Society was instrumental in attempting to test Darwin's subsidence theory by supporting three expeditions to Funafuti, Ellice Islands (now Tuvalu; see *Funafuti Atoll*), between 1896 and 1898, albeit inconclusively (Royal Society, 1904; Spencer et al., 2008). In the early twentieth century, the Society provided financial support for the 1928–1929 Great Barrier Reef Expedition, which set new standards for field-based coral reef physiology, ecology, and geomorphology; in addition to its leader, C.M. Yonge, four other expedition members became Fellows of the Society (F.S. Russell (1938), S. Manton (1948), T.A. Stephenson (1951), and S. Marshall

(1963)). From 1956 onwards, The Society has supported coral reef research through what since 1964 has been known as the Southern Zone Research Committee. The Committee organized the 1965 expedition to the British Solomon Islands Protectorate (leader: E.J.H. Corner (FRS 1955)); jointly with the Royal Society of New Zealand, the 1969 Cook Bicentenary Expedition to Tonga and the Southern Cook Islands (Stoddart and Gibbs, 1975); and the 1971 Royal Society–Percy Sladen expedition to the New Hebrides. In 1973, jointly with the Universities of Queensland, Australia, the Society organized a largely geomorphological expedition to the northern Great Barrier Reef (leader: D.R. Stoddart), in part revisiting the field sites of the 1928–1929 expedition (Figure 1).

Since the 1960s at a smaller scale, funds from the Society have also been used, *inter alia*, to support reef research in the Maldives (at Addu Atoll), Amirantes and southern Seychelles, and Diego Garcia in the Indian Ocean; and in the Phoenix Islands, Austral Islands, and Northern Cook Islands in the Pacific Ocean. In 1966–1967, the Royal Society was centrally involved in opposing U.K. Government plans to build a military base on the relatively undisturbed raised limestone island (and now World Heritage Site) of Aldabra Atoll in the south West Indian Ocean. Following an initial ecological inventory and expeditionary phase between 1966 and 1969, the Society built and administered the Aldabra Research Station between 1971 and 1979 before handing over its responsibilities to an independent trust, the Seychelles Island Foundation. It has been estimated that the Society supported the equivalent of over 50 person-years of research effort into physical and ecological monitoring

**Royal Society of London, Figure 1** Members of the 1973 Great Barrier Reef Expedition outside the Royal Society's rooms at Carlton House Terrace, London, prior to the Discussion Meeting of 28–29 January 1976. and experimentation at Aldabra, making it probably the most intensively studied atoll ecosystem in the world (Westoll and Stoddart, 1971). Finally, between 1998 and 2001, the Society, through its Environmental Research Programmes and in partnership with the Royal Geographical Society of London, supported the Shoals of Capricorn Marine Research Programme in the western Indian Ocean (Spencer et al., 2005).

## Summary

From its earliest beginnings in the seventeenth century, the Royal Society of London has promoted the interdisciplinary exploration of the reef seas, particularly in the Southern Hemisphere. The Society, both as a body and through the individual research activities of its Fellows, has made major contributions to the study of physical and geological oceanography; the establishment of the tectonic histories of coral reefs, both in the mid-ocean basins and on their margins; and the understanding of the biogeography and ecology of coral reefs.

## Introduction

Ryukyu Islands located in the northwestern Pacific at South Japan, latitudes between 24° and 30°50'N, longitudes between 123° and 131°E (Figure 1). The coral reefs

**Ryukyu Islands, Figure 1** Topographic map of the Ryukyus. Hatched line indicate the major route of Kuroshio Current and a branch current of Tsushima Current based on the sea surface current at 50 m depth line for November 2009 calculated by Japan Meteorological Agency. YK: Yonakuni Island, IR: Iriomote Island, IS: Ishigaki Island, S: Sekisei Reef, MK: Miyako Island, IB: Irabu Island, KM: Kume Island, OK: Okinawa Island, N: Nakagusuku Bay, YN: Yoron Island, OE: Okierabu (Okinoerabu) Island, TK: Tokunoshima Island, AO: Amami Oshima Island, KI: Kikai Island, YK: Yaku Island, TN: Tane Island, and MG: Mage Island. Depth in meters.

develop at high latitude because of the major western boundary current, Kuroshio Current flows through the Ryukyu Islands. The Kuroshio Current originates from the Western Pacific Warm Pool (WPWP) and flows through a part of “coral triangle,” the major marine biodiversity center in the Southeast Asia. Consequently, Ryukyu Islands are one of the richest multitaxon centers of endemism in the world’s coral reefs (Roberts et al., 2002).

### Geological setting

The Ryukyu Islands form an island arc parallel to the Ryukyu trench where the Philippine Sea plate subducts into the Eurasia Plate. Initial rifting of the back-arc basin Okinawa Trough occurs around 10 Ma after a major early Miocene change in the motion of the Philippine Sea plate (Sibuet et al., 1987; Furukawa, 1991). It ceased briefly during the Pliocene at 4 Ma, with a second rifting phase starting at about 2 Ma. Coral reef formation in Ryukyu Island started at the early Pleistocene (Yamamoto et al.,

2006) unconformably on the Tertiary Shimajiri Group, consisting mainly of siliciclastic siltstone.

At islands subjected to uplifting in the active margin, the reefs in the different time series are not overlapped and reef terraces are developed. Therefore, the major reef type in the Ryukyu Islands is fringing reef, with the exception of three barrier reefs due to local tectonic subsiding: the Sekisei Reef, 30 km × 20 km reef located between Ishigaki and Iriomote Islands; the Nakagusuku Bay, 20 km × 20 km reef located southeastern Okinawa Island; and the eastern Kume Island, 13 km × 6 km reef. The Holocene uplifted reefs have also developed in some islands subjected to active uplifting such as Kikai, Kume, Takara, and Kodakara Islands (e.g., Koba et al., 1979; Takahashi and Koba, 1977; Sasaki et al., 1998; Ota et al., 2000; Sugihara et al., 2003).

### Climate conditions

The average (1971–2000) monthly maximum in (minimum) air temperatures, annual rainfall, and average

monthly maximum (minimum) sea surface temperatures (SST) of the Ishigaki Island in the Southern Ryukyus, the Naha in the Central Ryukyus and Tane Island in the Northern Ryukyus are 29.3°C (18.3°C) 2,060 mm SST 29°C (23°C), 28.5°C (16.6°C) 2,037 mm SST 28°C (21°C), 27.7°C (11.7°C) 2,330 mm SST 28°C (19°C), respectively (Japan Meteorological Agency, 2009). The large latitudinal gradient occurs at the minimum air and sea temperature in winter. The difference in minimum SST creates the latitudinal gradient in coral reef development in the Ryukyus (Hori 1980).

Prevailing wind directions in Ryukyu Islands are NW to NE in winter and S to SE in summer (Japan Meteorological Agency, 2009) influenced by East-Asian monsoon. The typical windward/leeward reefs as in the trade wind zone are not found in the Ryukyus and fringing reefs are surrounding the islands due to the reversal of the windward by seasons. The Ryukyu Islands are also located at the horse latitude in the typical track of typhoons originating from the WPWP. Typhoons develop to a maximum strength and reducing speed around the Ryukyus. Storm surge at typhoons plays an important role on reef-edge sediments and boulders on reef flats in Ryukyus along with tsunami surge (e.g., Kawana and Nakata, 1994; Kan, 1995; Onda, 1999; Suzuki et al., 2008; Goto et al., 2009).

### Start-up growth of the postglacial reefs

In the Ryukyu Islands, a reef developed in the last glacial period was discovered by drilling an island shelf off the Irabu Island (Sasaki et al., 2006). This reef grew from 22 to 15 ka at the present depth of 126.2–123.2 m and gave up its growth with the postglacial sea level rise.

The modern reefs developed along the present shorelines began to grow in the Holocene period. In the Southern Ryukyus, the start-up growth of modern reef occurred around 8000 BP ( $^{14}\text{C}$ ) on the extensive antecedent platform around 20 m at Sekisei Barrier Reef (Kan and Kawana, 2006). On the Ishigaki Island, where fringing reef of 1–1.5 km width surrounds the island, reef started to grow around 7400 BP ( $^{14}\text{C}$ ) from around 20 m deep (Hongo and Kayanne, 2009).

In the Central Ryukyus, the modern reef started to grow around 8000 BP ( $^{14}\text{C}$ ) from 17 m deep in the southeastern Okinawa Island (Kawana and Kan, 1996, 2002) and 7900 BP ( $^{14}\text{C}$ ) from 15 m deep in the Kume Island (Takahashi et al., 1988; Kan et al., 1991, 2000). In the Okierabu Island, reef started to grow at 7500 BP ( $^{14}\text{C}$ ) from 10 m deep (Kan et al., 1995). The early start-up growth of around 10 ka and formation of 25 m-thick reef limestone has been reported in the Kikai Island (Konishi et al., 1978, 1983; Webster et al., 1998; Sasaki et al., 1998), where active uplift of 1.8 m/ka took place at least in the late Pleistocene (Ota et al., 2000; Sasaki et al., 2004).

In the Northern Ryukyus, the recent drilling research shows the lagged start-up growth around 6100 BP ( $^{14}\text{C}$ )

in the Mage Island at latitude in 30°45'40"N, where the maximum thickness of the Holocene reef is 4 m (Kan et al., 2006).

### Development of Holocene reefs and their zonation

When the sea level reached its present position of about 6500 BP (Alley et al., 2005), the wave-resistant structure, such as the present reef edge, had not been formed before the reefs grew to reach sea level (Figure 2b). The initial reef growth to reach the sea level lags at least 500–1,000 years behind sea level rise. Before the reef first reached the sea level, the strong wave condition was assumed for coastal zone because of less wave attenuation in reef (i.e., “Holocene high-energy window”). This condition causes the active coastal erosion to form bench and cliff along the uplifted Pleistocene limestone coasts and also sometimes induces the active coral growth landward.

The timing of the reefs that have reached the sea level varies from 6100 BP to around 4000 BP ( $^{14}\text{C}$ ) in the Southern and Central Ryukyus with the average upward growth rate of around 4 m/kyr (e.g., Takahashi et al., 1988; Kan and Kawana, 2006) mainly by corymbose coral community (Hongo and Kayanne, 2010). The primary growth of the reefs usually with tabular corals acted as a breakwater and differentiated the reef into a fore-reef zone and a back-reef zone (Figure 2c). The reef first reached sea level forming the reef crest ridge of the present reef and is interpreted as the functional core for reef zonation.

After the crest growth, the back reef, especially seaward of the lagoon, was infilled by thickets of in situ ramose corals and accumulation of coral debris derived from the reef edge (Figure 2d). The vigorous back reef accumulation up to 10 m/kyr ends up about 500 to 1,000 years after the crest growth (Takahashi et al., 1988; Kan and Hori, 1993).

Simultaneously, the area of active reef growth has shifted progressively seaward with the development of reef edge spurs. The micro-topographic units along reef margins such as spurs, grooves, and reef tunnels are formed in this stage. The pinnacles in front of the established spur and groove system reach sea level and the reef margin migrate seaward (Figure 2e). This gradual process is called “reef flat accretion” (Kan and Hori, 1993) and has contributed to the build-up of expanded reef flat under almost stable sea level condition in the late Holocene.

The strong zonal patterns emerge when the energy-related gradient develops. In the middle Holocene, the reef first reached the sea level, which acted as a breakwater and differentiated the reef into a fore-reef and a back-reef. The fringing reef lagoon may have been formed by a damming process where the growth axis is located some distance offshore. The initial growth axis forms the reef crest ridge of the present reef and is interpreted as the functional core for reef zonation.

**Ryukyu Islands, Figure 2** Development of modern fringing reef in the Ryukyus. The base diagram is after Kan (2001, 2007) for typical “crest – lagoon” reefs. The accretion style and ages are based on the drilling and trench-wall results in Kume and Minna Islands in the Central Ryukyus. (1): in situ tabular/plately/massive coral framework, (2): rounded coral crusts accumulated in grooves, (3): branching corals and/or platy coral crusts, (4): loose sandy sediments with coral rubble, (5): rubble bed accumulated at the depressed reef substrate.

### Latitudinal gradient in reef geomorphology

The width of reef flats narrows with increasing latitude in the Ryukyu Islands. Changes in reef morphology do not occur gradually but are regionally selective, especially in the width of shallow lagoons that disappear as reef flats become narrower. Hori (1980) used the term “reduction” for the decline in zonation and width of reef flats. The coral species diversity also decreases in higher latitude with loss of the reef geomorphological diversity (Veron, 1992; Nishihira and Veron, 1995).

In the Okierabu Island (27°20'N) in the Central Ryukyu Islands, reef flats are significantly narrower than those in the other islands at similar latitudes where shallow lagoons have not been formed. The reef has been constructed by a uniform facies of in situ tabular corals, which shows that the reef has not experienced any cross-reef energy gradient

(Kan et al., 1995). In the case that the initial growth axis lies at the landward end, the reef experienced no energy gradient during its formation, thus the flat topography with obscure zonation is formed by the following “reef flat accretion” process in the late Holocene.

The width of the reefs are reduced to 100–300 m, partially 500 m in latitudes more than 27°20'N. At the northern limit of the entire reef surroundings of the island is the Kodakara Island located at the latitude 29°13'N. North of this latitude, the reef distributes a part of the coastline. The typical acroporid reef in the Ryukyu Islands gradually disappears around 30°N.

### Summary

The relatively late start-up growth of modern coral reefs in the Ryukyu Islands may be due to the main flow of the

Kuroshio Current inferred to reentering into the East China Sea around 8600 BP ( $^{14}\text{C}$ , Diekmann et al., 2008) along with the high-latitude locality of the archipelago. The development of modern reefs shows the distinct latitudinal gradients in size and distribution until around  $30^{\circ}\text{N}$ . The reef founded in the Iki Island at  $33^{\circ}48'\text{N}$  is a favid reef (Yamano et al., 2001) partially distributing in the area. It is different from the series of acroporid reefs in the Ryukyu Islands and there is a gap of reef development between  $30^{\circ}\text{N}$  and  $33^{\circ}48'\text{N}$ . The gradually disappearing of modern reefs at high latitude along Ryukyu Islands is unique in the global coral reef distribution.

## SCLERACTINIA, EVOLUTION AND TAXONOMY

---

John E. N. Veron  
Coral Reef Research, Townsville, QLD, Australia

### Definition

Evolution is a widely ranging subject, involving the fossil record, the taxonomic and systematic organization of extant taxa, and the genetic processes that appear to have given rise to those taxa. This article summarizes the main events in the evolution of modern corals, outlines the nature and variation in extant species, and reviews the evolutionary mechanisms most relevant to corals. These are the processes that lead to the taxonomic organization of species and give rise to the taxonomic issues which coral researchers inevitably face.

### Fossil record

The first organisms that might be called scleractinians are known from Paleozoic fossils from China and Scotland (Ezaki, 1998), but the earliest proliferation of organisms that were clearly ancestral Scleractinia are Middle Triassic and consisted of at least seven, but possibly nine, suborders. These corals did not build reefs; they were small solitary or phaceloid organisms of the shallow Tethys of southern Europe and Indo-China (Stanley and Fautin, 2001; Stanley, 2003).

During the Middle and Late Triassic, corals became widespread throughout the Tethys region and their fossils are now found around much of the equatorial Panthalassa Ocean rim. There was an enormous time interval of 20–25 million years between the earliest Triassic corals and the earliest widespread coral reefs. Most noteworthy of Triassic corals is that they had a wide range of skeletal microstructures, suggesting that any common ancestry would

have been remote. Nevertheless, Triassic corals were not the ecological equivalents of modern corals; corallites were large and poorly integrated so that phacelloid growth forms (where branches are composed of individual corallites) were dominant.

There was a 5–8 million year hiatus between the collapse of Triassic reef development and the onset of Jurassic reefs, a time of origin of many new scleractinian families (Beauvais, 1989). The Late Jurassic was probably the all-time global maximum of Mesozoic coral diversity with at least 150 genera recorded in the European Tethys and 51 in the Panthalassa. Paleobiogeographic provinces can be recognized which reflect continental plate movements, especially the increasing width of the Protoatlantic. By the Late Jurassic the paleobiogeographic pattern that had developed was the precursor to the pattern that persisted into the Cenozoic. It was dominated by massive reef development throughout the Tethys, the Atlantic, and also the far eastern Panthalassa. The vast expanse of the eastern Panthalassa was probably a barrier to east-west dispersion, just as the far eastern Pacific is today.

A high proportion of the families of extant Scleractinia have their origins in the Middle to Late Jurassic. For most, the fossil record is not clear, and thus there are few links between the main branches of the Family Tree (Figure 1). The Jurassic was the time of the proliferation if not origin of two of the most major groups of corals, the Fungiina and the Faviina. The Fungiina dominated much of the Jurassic as well as the Cretaceous. As a group it was greatly diminished by the end-Cretaceous mass extinctions and the families attributed to it today have uncertain affinities. The Faviina, on the other hand, are a well-defined group and the Faviidae have remained a major family for 150 million years.

Early Cretaceous corals are broadly similar to those of the Late Jurassic (Beauvais, 1992). However, relatively little is known of the Middle Cretaceous corals. The

**Scleractinia, Evolution and Taxonomy, Figure 1** The 'Family Tree' of Scleractinia. Reconstructing the evolutionary sequences of Scleractinia is a complicated process for it must encompass the fossil records over very great intervals of time, the taxonomic relationships of extant corals, and studies of coral systematics using molecular techniques. The top of the 'tree' (the families of extant corals) is well established, as are the main branches through the Cenozoic, since most of these have extant representatives. However, little is known about the Mesozoic ancestors of Scleractinia, for the majority of families are extinct (simplified from Veron, 2000).

continuity of families indicated in Figure 1 is largely due to extrapolations between Early and end-Cretaceous fauna, with poorly-known families omitted. This is because, by Middle Cretaceous, reefs worldwide had become dominated by rudist bivalves and environmental perturbations greatly affected reef development. It was not until the very late Cretaceous, following an unexplained total extinction of the rudists, that corals returned to a position of dominance. At this time reefs probably again occurred worldwide, but there are few remains of them today.

One-third of all families and over 70% of all genera became completely extinct at the end-Cretaceous boundary. The Faviidae and the Caryophylliidae are the only families that were major component of Mesozoic reefs that also proliferated in the Cenozoic (Veron, 1995).

The evolutionary history of modern corals is divisible into three geological intervals (1) the Paleogene, when the few survivors of the end-Cretaceous extinctions proliferated into a diverse cosmopolitan fauna, (2) the Miocene, when this fauna became subdivided into the broad biogeographic provinces we have today and pre-cursors of most extant species evolved, and (3) the Plio-Pleistocene to present, when the world went into full glacial mode and modern distribution patterns emerged.

For 12 million years after the end-Cretaceous extinctions, only thirteen new genera of corals have been recorded. It was thus a radiation of new zooxanthellate genera that populated the seas of the Eocene. By Late Oligocene, reef development became world-wide and diversity reached an all-time high in the Tethys and Caribbean (Frost, 1981).

The Miocene is the time of origin of non-Oligocene extant genera (primarily Indo-Pacific) and the immediate ancestors of extant species. It is also the time of obliteration of the Tethys, the extinction of non-zooxanthellate corals from the Mediterranean, and the start of the separate evolutionary histories of Atlantic and Indo-Pacific species.

Compared with most other major groups of animals, coral genera are long-lived in geological time and have low extinction rates: nearly half of all extant genera extend

as far back as the Oligocene and nearly  $\frac{1}{4}$  extend back to the Eocene.

The history of corals subsequent to the Miocene (Veron, 1995) becomes decreasingly visible in the fossil record and increasingly visible in the taxonomy and distribution of living corals. The Plio-Pleistocene fossil record of the Caribbean is better than that of the Indo-Pacific and it is in the Caribbean that the impacts of the Pleistocene glaciations were greatest. The progressive closure of the Central American Seaway was one of the most important events in the history of modern corals. Before the closure there may have been no distinction between the corals of the far eastern Pacific and those of the Caribbean. After the closure (3.4 my BP), the corals of the Pacific side of the Isthmus were extinguished, or nearly so.

There are no zooxanthellate scleractinian species common to the Indo-Pacific and the Caribbean today.

### Species variation

Like most plants, corals have morphological characteristics that vary according to (a) the environment in which they grow, (b) their geographic location, and (c) genetic links among component populations.

### Environmental variation

Most colonial corals show morphological variation within the one colony. Colonies of some species have variable growth forms which are at least partly genetically regulated independently of environment. However, most species exhibit variations that are clearly associated with different parts of the colony having different micro-environments. Differences among micro-environments include growing space, light availability, sedimentation, and fish grazing. The morphological variations that result affect both growth form and corallite structure (Figure 2).

Different colonies (or individuals) of all coral species vary along environmental gradients (Figure 3). Divers can readily see this happening as they descend down a reef slope. This variation is also seen if a coral is transplanted from one habitat to another. It will usually change its

**Scleractinia, Evolution and Taxonomy, Figure 2** Variation in the structure of corallites in a single specimen of *Porites lutea* ( $\times 10$ ) (After Veron, 1995).

**Scleractinia, Evolution and Taxonomy, Figure 3** Variation in the skeletal structure of colonies of *Pocillopora damicornis* from a wide range of habitats at a single geographic location (After Veron, 1995).

appearance to reflect the conditions of the new habitat. Most plants do likewise; these responses are not under direct genetic control, although particular genotypes may be associated with particular morphologies.

The most important environmental factors controlling growth form are exposure to wave action, levels of illumination, sediment load, and exposure to currents. The different morphologies that result must be accommodated by taxonomic descriptions and understood by persons identifying corals.

### Geographic variation

There are two distinct categories of geographic variation in corals: those which are the outcome of environmental factors, and those which are genetic. Geographic variation that is the outcome of environment is best seen in high latitude coral communities where low temperature and non-reef habitats result in colonies being distinct from their tropical reef-dwelling counterparts. Likewise, there are whole geographic regions where the water is almost always clear (such as the Red Sea or Bahamas) and other regions where the water is usually turbid. Corals from these regions commonly have distinct points of morphological detail that are primarily due to environmental differences.

Geographic variation that is genetically based affects almost all species in some way or other. Again like most plants, the appearance of a single species changes (gradually or abruptly) from one region to the next. These changes may not concern those who are only interested in the species of a single country, but they will definitely concern anybody who tries to identify corals over a wide geographic range. Of more practical importance, it raises significant issues for those who try to identify a species in one country from information about that species from another country.

### Genetic links among populations

It is common for a series of adjacent colonies of the same species, in the same environment, to display a wide range of colors and to have a variety of morphological differences. In such cases, the presence or absence of morphological continuities among colonies, or populations, can be used to distinguish groups of species (commonly called 'sibling species') from a single variable species (commonly called 'polymorphic species'). Although the differences seen are widespread, intermediate colonies can usually be found.

Genetic bridges and barriers generate reticulate patterns in time and space (see below), patterns which maintain the

species' genetic heterogeneity. The taxonomic issues that arise are of endless complexity. They inevitably lead to the conclusion that there are no fundamental differences between species and subspecies taxonomic levels.

### Evolutionary mechanisms

What happens to geographically variable species in evolutionary time? The issues that arise are not just theoretical. They make it necessary to consider evolutionary change in a way that is very different from that which is generally accepted in both popular and scientific literature. This introduces reticulate evolution, a concept fundamentally distinct from neo-Darwinian evolution, one that involves a different way of looking at what species are and how they change.

### Reticulate evolution

Evolutionary change can seldom be observed directly: it must be re-constructed, as is commonly done using phylogenetic trees (such as [Figure 4](#)). Trees are also one way of envisaging reticulate evolution. Such a tree might have a main trunk for the family, several large branches for genera, and many fine branches for the species. Species that

are currently alive will be the tips of the uppermost branches, and these will be trimmed to uniform height to represent present time. The branch tips, each representing a single species, can be converted into distribution maps, each map representing the present-day distribution of one species. If a single branch (or species) is then sliced into a sequence of horizontal layers, and each layer is turned into a distribution map, each map will indicate the distribution of the species at progressively distant points in time. If the maps are viewed like the pages of a book, the pattern will change sequentially back in time. These changes will not be just distribution changes, they will also be genetic changes occurring in response to changes in ocean currents. As a result, a species (or map) at one point in time is not the same as it is in another point in time: it has been genetically as well as geographically changed. These changes do not occur uniformly, they occur irregularly over the species' geographic range and evolutionary history. Geographic space and evolutionary time interact. The species may break apart, then re-form into a slightly different species. This creates a 'reticulate' pattern in both geographic space and evolutionary time (Veron, 2002).

**Scleractinia, Evolution and Taxonomy, Figure 4** A hypothetical view of reticulate evolutionary change within a group of species. At the bottom (Time 0), the group forms three distinct species each of which is widely dispersed by strong currents. At Time 1, the group forms many indistinct small species units that are geographically isolated because currents are weak. At Time 2, the group forms three species that are again widely dispersed by strong currents. Over the long geological interval to Time 3, the group has been repackaged several times (After Veron, 2000).

As [Figure 4](#) illustrates, basic issues that arise with reticulate evolution are: (a) no species has a time of origin, (b) rates of evolution and extinction are similar over the geological interval represented by the diagram, (c) there are no differences between mainstream species (represented by the thicker branches) and subspecies (represented by thinner branches), (d) there are no differences between 'species' and 'hybrids', (e) the total amount of genetic information represented by the diagram has not greatly changed over time, but has been re-packaged into different 'species' units, (f) extinction occurs through repackaging as well as terminations of lineages.

#### *Ocean currents and reticulate patterns*

Ocean currents are the vehicle of dispersion and the pathways of genetic connectivity. When a species breaks apart (as a result of weak ocean currents) it becomes many species. When it re-forms (as a result of strong ocean currents) it may again be a single species or it may be more than one species. It may also contain genes from other species. This is reticulate 're-packaging', and it occurs constantly at all scales of space and time. Importantly, the re-packaging is not confined to a single phylogeny, it involves many phylogenies simultaneously ([Figure 5](#)).

Reticulate evolution is under physical environmental control, not biological control. The physical control changes patterns of genetic connections: it acts on genetic composition. This is again in sharp contrast with a major aspect of the neo-Darwinism where evolution is primarily

controlled by competition between species, a process that creates morphological changes. Reticulate evolution is therefore a mechanism of slow arbitrary change rather than a mechanism for progressive improvement.

Reticulate evolution is primarily driven by changes in surface circulation patterns causing changes to the dispersal patterns of larvae. If currents remained constant throughout evolutionary time, the oceans would be divisible into source areas (where larvae come from) and destination areas (where larvae go to) and geographic gradations within species would be generally predictable. However, with the exception of the great ocean gyres, currents are not constant. Sea levels may fluctuate over 100 m, oceanic passages are opened and closed by tectonic movements, and the Earth goes through cyclical climate changes due to variations in the Earth's orbit around the sun. These, and probably several other types of geoclimatic cycles, cause variations in ocean currents. These changes open and close genetic contacts: they generate reticulate patterns.

The concept of reticulate evolution is highly explanatory of the observations about coral taxonomy and biogeography. It is also strongly supported by all that is known of coral reproduction and is starting to be supported by genetic studies.

The main points illustrated by [Figure 5](#) are as follows. At Time A, currents are strong and the phylogeny exists as a single widespread species. At Time B, currents are weak and the phylogeny has broken up into six

**Scleractinia, Evolution and Taxonomy, Figure 5** A hypothetical view of evolutionary change in a small phylogeny (left) correlated with distribution patterns (maps, right) (see text) (After Veron, 2000).

geographically isolated indistinct or 'sibling' species. (Two of these species (labeled 2 and 3) are doomed to subsequent extinction.) At Time C, currents are strong again and the phylogeny has been re-packaged into two widespread species, which are reproductively isolated. The species on the right is part of the phylogeny of another species. Importantly, there is no distinction between geographic (sympatric) and non-geographic (allopatric) origination, evolution is driven by environmental change, not biological competition (Veron, 2000).

### Competing hypotheses

Theories of biogeography and evolution have always been inter-related. Historically, there have been five main schools:

#### *Darwin's centres of origin*

Darwin (1859) proposed that dispersion was primarily driven by the evolution of new species through natural selection, where older and less competitive species are displaced away from centers of origin to more distant places by fitter and more competitive, descendant species. This is but one aspect of Darwin's theory of the origin of species, yet is one of his most thoughtful for it integrated the known distribution of many plant and animal groups with their fossil record.

Darwin's Centres of Origin theory, or refinements of it, dominated all coral biogeographical thinking until the theory of continental drift appeared to make a fundamental aspect of it – geographic centres – untenable (Briggs, 1984). Interest in this theory, at least as far as corals are concerned, is historical for there are no identifiable centres of origin, only centres of diversity.

#### *Croizat's panbiogeography*

Panbiogeography is very much the subject of Leon Croizat, biogeography's most prolific writer and an outspoken opponent of both Darwin's Centres of Origin and vicariance biogeography (see below) (Croizat, 1981). Panbiogeography is primarily a method (rather than a theory) where 'road maps' of taxa are superimposed to produce 'dispersion highways' (Craw, 1988). The intersection of many highways denotes the existence of 'gates' or 'nodes'. These are places of high connectivity from which dispersion occurs.

Panbiogeography has more relevance to terrestrial life than marine where the base map effectively changes with the vagaries of palaeoclimates, ocean currents and long-distance dispersal (Craw and Weston, 1984).

#### *Vicariance biogeography*

Vicariance biogeography was a major advance on Darwin's Centres of Origin (McCoy and Heck, 1976). It is based on the notion that if one or more barriers form across a species' distribution range, the divided population will diverge in time, forming two or more distinct populations. If these become reproductively isolated they would be two or more distinct species when the barriers

are removed. This process on a large scale would lead to patterns of species that have no centre of origin. Importantly, there is no requirement for dispersion to occur.

Vicariance speciation requires that an ancestral species occupies the geographic area of its descendants and that this area becomes divided up as those descendants progressively evolve. The process, therefore, produces ever-increasing numbers of species, each occupying an ever-decreasing geographic range. The result is ever-increasing endemism, hence a close association between the concepts of endemism and vicariance.

There are significance arguments against vicariance as a general principle in coral biogeography: (a) dispersion is actually of overwhelming importance to corals, (b) the place of origin of coral species is not correlated with place of occurrence, (c) the process of evolutionary change neither commences nor ceases in any particular point in time and (d) there has been no exponential increase in numbers of coral species in any geographic area. On these grounds vicariance cannot be accepted as an evolutionary mechanism in its own right. More importantly, it follows that cladistics as an analytical method must also lead to faulty conclusions as both vicariance and cladistics are based on the same supposition that there is no lateral gene flow (or hybridization) among the species under question (Hennig, 1966; Sober, 1988). Put another way, both vicariance and cladistics are predicated on the absence of syngameon formations (see below).

#### *Dispersion and the founder principle*

The concept of dispersion biogeography, proposed by Mayr (1942) and expanded by Carson (1971), is based on the notion that a species may come to occupy a previously unoccupied place through dispersion (a 'founder' event). It may then be genetically isolated by the formation of a barrier and in time form two or more species. As with vicariance, speciation is allopatric and the outcome is seen in patterns of endemism. The main difference between this theory and vicariance is that this theory requires dispersion to occur and vicariance requires dispersion not to occur. If species co-occur after speciation, additional dispersion is equally necessary for both theories.

Dispersion biogeography is generally linked with Centre of Origin biogeography as the alternative to vicariance (Simberloff et al., 1981) but, as with so much biogeography, this highlights extremes rather than common ground. In reality, most evolutionary issues concerning spatial separation between populations of the same species are irrelevant to corals because of their capacity for long-distance dispersal.

#### *Equilibrium theory*

The equilibrium theory of island biogeography (MacArthur and Wilson, 1963, 1967), an essentially ecological theory, had a major impact on biogeographic concepts when it was first proposed. When rates of immigration to an island are balanced by local extinction, the number of

species (but not necessarily the identity of those species) remains approximately constant. For any particular island there is a dynamic balance between immigration, local extinction, proximity to a continental mainland, and the area of the island. Equilibrium theory has largely gone out of fashion although it is a useful concept for zooxanthellate corals on a regional scale.

### Where reticulate evolution and Darwinian evolution meet

The theory of reticulate evolution, alone among its many rivals, requires no geographic restrictions, does not depend on barriers forming or going and does not result in changes in species diversity. At least as far as corals are concerned, the theory provides a sound reason for observable taxonomic dilemmas (below), is seen in biogeographic patterns, is genetically sound, is reflected in the fossil record and accords well with reproductive biology. As such, reticulate evolution appears to be in direct conflict with Darwin's concept of evolution by natural selection and survival of the fittest, which is at the heart of his almost universally accepted general theory of evolution.

However, these two theories are compatible. It can reasonably be supposed that most life, terrestrial as well as marine, does not exist as reproductively isolated species but rather as syngameons of some sort. (This is seen, for example, in domesticated plants and animals, almost all of which can be artificially hybridized.) These syngameons can undergo change through reticulate evolution, but not natural selection. However, depending on many circumstances, individual species (or genetic units of any kind) may become temporarily genetically isolated, perhaps through the formation of an environmental barrier. If these isolated units become genetically cohesive they would then be able to respond to selective pressure and would be able to undergo Darwinian evolution. The level of isolation required would be unendingly variable among different taxa. If the unit continued to remain isolated it may continue to evolve as a single species or develop into a syngameon. Alternatively, the newly formed unit may in time merge back into the syngameon from which it came. In this case, it will cease to evolve through natural selection. There is, of course, an almost infinite array of such possibilities in the dynamics of life.

### Taxonomy

For over 100 years, species have been considered to be the building blocks of Nature, blocks that have a time and place of origin, which can evolve, and which maintain themselves as discrete entities by being reproductively isolated. This is a logical concept, but one which breaks down, for corals at least, when confronted with the realities of taxonomy and geographic variation. The alternative, where most species have none of these attributes, is initially less intuitive but ultimately is highly explanatory of what can actually be observed in the real world.

### Traditional concepts of species

Concepts of what species are have long been debated, a debate driven as much by misinterpretation as information. This debate has mostly been ignored by taxonomists (who often believe they 'know' what their species are for one reason or another) as well as most other biologists (who often consider it armchair philosophy and thus largely irrelevant to the needs of reality). Be that as it may, species have variously been considered to be (a) self-defining natural units, (b) human-defined units composed of assemblages united by common descent, or (c) genetically-defined units resulting from Darwinian natural selection and/or reproductive isolation. The last involves a group of concepts about species, sometimes called the 'neo-Darwinian synthesis' or the 'biological species concept' (depending on a wealth of detail) that embodies the notions of the building blocks referred above.

### Classification

Forty years ago, museum displays provided much of the scientific basis of what was then known about coral species. The specimens came from voyages of discovery from the tropical world, and they mostly went to the museums of Europe, Japan, and America. At that time, each new form was described as a new species and given a Latin name. Where major collections were made in a single country, the corals were usually given a name that, in practice, had relevance to just that country. As a result, an account of the 'Corals of Japan' was quite different, for example, from an account of the 'Corals of the Marshall Islands', or wherever else.

These accounts were often very different, the main reason being that taxonomists of the time did not have the advantage of scuba diving, thus they had little opportunity to study corals in any natural habitat other than reef flats. They could not, for example, see how a single species gradually changes its growth form down a reef slope in response to decreasing light and turbulence. Most coral taxonomists (and there were many of them) simply concluded that any distinctive growth form was a distinct species.

In all, about 400 taxonomic publications about reef corals, and descriptions of some 2,000 'nominal' species (species in name if nothing else) stem from the pre-scuba era. The issues this raises are many, for the rules of nomenclature state that in most cases the oldest name given to a species is the 'correct' name. Unfortunately, that frequently means that the 'correct' name is based on a poorly described specimen from an unknown environment and sometimes from an unknown country. The author of a new species in those days usually had no concept of what a species might actually be, and they usually had no idea of how their species might vary with environment.

Modern coral taxonomy appears to follow the path of its predecessors, but this appearance is superficial. Taxonomy has become the servant of other disciplines and must

therefore incorporate the many forms of morphological and genetic variations within species that occurs in responses to environment and geographic distance. It should also incorporate, as far as possible, the existence of syngameons.

### *Syngameons*

The concept of the syngameon, first recognized by botanists (Grant, 1981) and introduced to the marine world through corals (Veron, 1995), is important for the understanding of the evolutionary mechanisms of corals and the geographic patterns they form. A syngameon, by definition, is a reproductively isolated unit. In concept, so are neo-Darwinian species. In reality, syngameons are nothing like any of the concepts of species referred to above as they incorporate geographic variation and the spectrum of genetic links geographic variation creates among different species (Figure 6).

A syngameon may be a single species, or it may be a cluster of different species which have variable genetic links with other members of the syngameon. Where a syngameon contains several species, a single component species may be distinct at a single geographic location but, because it intergrades with other species at other locations, it will become submerged in a mosaic of variation at other locations. The geographic range and morphological variation of the single 'species' will depend on taxonomic decisions. These decisions will be arbitrary if they impose divisions in natural continua rather than reflect natural units. The syngameon as a whole is not morphologically visible unless its component species are determined genetically or experimentally (through cross-fertilisation trials) in every part of the species' possible distribution range (Veron, 1995).

### *Taxonomic issues*

Geographic variation is far more difficult to study than environmental variation as knowledge of it must be

**Scleractinia, Evolution and Taxonomy, Figure 6** Conceptual paths of gene flow of a single species. Some populations in a species' distribution range are downstream from all other populations. However, most populations import genetic information from upstream locations and export it to downstream locations. This process creates geographic variation within the range of the species and ultimately is responsible for the formation of syngameons (After Veron, 2000).

accumulated from separate studies in different countries: it cannot be directly observed. The main taxonomic issues are: (a) species become progressively less recognizable as single units with increasing geographic range, (b) taxonomists are forced to make arbitrary decisions, (c) synonyms vary geographically. In each case, the more detailed a taxonomic study is, the greater the problem becomes.

### *Taxonomic certainty and geographic range*

With corals as with most plants, most species *do* exist as more-or-less definable units in single geographic regions, such as the Red Sea, the Indonesian/Philippines archipelago, the Great Barrier Reef or the Caribbean. However, widespread species commonly show sufficient geographic variation that they could reasonably be divided into several separate 'sibling species' were it not for the fact that these smaller units form continua. Thus, for example, the majority of species of the Red Sea also occur in Indonesia, but many are sufficiently different in the Red Sea that they would be considered to be distinct species if they were transplanted from the Red Sea to Indonesia (Figure 7).

### *Arbitrary decisions*

In theory, taxonomy should accommodate biogeographic patterns. In practice, doing so creates issues like those created when a flat map is projected onto a sphere. The bigger the area of the map, the greater the distortion that results. It is possible to modify the flat map using different types of projections, but this only changes the nature of the distortion.

In traditional taxonomy, geographic variation within a species is accommodated by creating divisions within the species, such as varieties, races or geographic subspecies. In reality, geographic variation repeatedly overrides the morphological boundaries of individual species. In other words, natural continua go beyond the taxonomic or morphological boundaries of single species. This cannot be accommodated by creating divisions within species. The problem remains if the species unit is 'split' into smaller units or 'lumped' into larger units, and it is not solvable by further or more detailed study. Ultimately, the only unit in Nature that is real is the syngameon referred to above.

The reasons why syngameons are not used in taxonomy are (1) they can only be determined with any degree of certainty through exhaustive cross fertilization studies in all geographic regions where their component species occur, (2) they are not likely to have distinguishing morphological characteristics, and (3) they would include so many morphological species that they would need to be re-divided into sub-units of some kind in order to be useful.

This issue will always force taxonomists to make an arbitrary decision as to what a particular species is. Some groups of species may be distinctive in some geographic regions and not in others. The outcome of detailed studies of these species may either be a single 'species complex' or a group of similar species. In either case, species descriptions and distribution maps artificially simplify the reality of the complex.

**Scleractinia, Evolution and Taxonomy, Figure 7** Geographic variation from a taxonomic point of view. A species that is taxonomically straightforward in the central part of its range (area 1) may have morphological uncertainties in more peripheral parts (area 2) and form distinct subspecies at extremities (area 3) (After Veron, 2000).

### Geographic variation in synonymies

Synonymies are intended to clarify the taxonomic history of an individual species and as such are commonly considered to be a formal statement about the status of that species. However, if species can vary geographically it follows that detailed synonymies may also vary geographically. In practice, this consideration is seldom taken into account.

### Summary

The above considerations argue that the term 'species' can legitimately have a wide range of meanings. Within a single region, species are usually morphologically distinguishable from other species and are genetically semi-isolated from other species. Over their full geographic range, species vary morphologically and genetically and are not necessarily morphologically or genetically isolated from other species. Geographic patterns of species combine with distribution changes to produce networks of genetic links. These links are not observable in single geographic regions and for this reason are not generally recognized in taxonomic studies of corals or most other groups of organisms.

In theory at least, corals vary according to the spectrum of habitats they occupy, the size of their geographic range, and the extent of gene flow within that range. In practice, variation that is correlated with habitat (such as the variations of *Pocillopora damicornis*, [Figure 3](#)) can be satisfactorily described and illustrated so that the species is a single identifiable unit. However, genetic variation defies the use of units if they merge with other units. When this happens, the units can only have arbitrary boundaries. This certainly happens with corals and probably does so with most other marine life.

General principles about species over large geographic ranges are: (1) their geographic boundaries merge with other species, (2) their morphological boundaries merge with other species, (3) there are no definable distinctions between species and subspecies taxonomic levels ([Veron, 1995](#)).

Nature, therefore, is mostly composed of continua in space and time, continua which will always defy human attempts to make taxonomic units. If taxonomists create units (as they must if their taxonomy is to be meaningful) it must be remembered that these units are artificial: they lack discrete morphological boundaries, and they also lack discrete geographic boundaries. Also, as our knowledge of coral biology increases, it is becoming clear that the ecological, physiological, and reproductive characters of individual species also vary geographically. It is a human dilemma that we need taxonomic units at all to communicate information about Nature's organization, when Nature is not necessarily divided into units of any kind.

### Acknowledgments

The author thanks Dr. M.G. Stafford-Smith for critically reviewing the manuscript.

Coral chronometers; Related to Dendrochronology

### Definition

**Sclerochronology:** The term sclerochronology is derived from the Greek words *sklero*, meaning “hard,” and *chronos*, meaning “time.” The field of sclerochronology is the study of periodicities stored in accreted hard parts and skeletons of various extant and extinct organisms. The periodicity can range from daily to annual scales and compose chronologies that span years to centuries, thus providing potentially long records of historical variations. Annual periodicity provides a chronology for determining age, growth rates, and reconstructions of environmental influences. Along with the recorded growth chronologies, the chemical composition of the skeleton also contains temporal records based on isotopic ratios and trace elemental concentrations, which can be used to reconstruct proxy paleoenvironmental and paleoclimatic records. Studies of skeletal growth and geochemical records have been used within the broader fields of ecology, physiology, and paleoclimatology. Sclerochronology is akin to the study of annual growth rings in trees, termed dendrochronology.

### Introduction

Sclerochronology encompasses a wide array of organisms within coral reef environments that secrete structures which reflect growth periodicities. These may include, but are not limited to: corals, mollusks, fish, and sclerosponges. The following description is constrained to coral sclerochronology to provide a more focused perspective within the broader field of sclerochronology. It should be noted that early developments in mollusk sclerochronology (Isely, 1913, 1931; Orton, 1923; Davenport, 1938; Bonham, 1965) and fish sclerochronology (Leeuwenhoek, 1685; Pell, 1859; Adams, 1940; Jackson, 2007) paralleled the advances in coral sclerochronology, but because the nature and skeletal correlates of annual records differ substantially between taxa and phyla, descriptions and methods are generally specific to each subfield of sclerochronology.

Scleractinian corals are colonial organisms that secrete calcareous skeletons composed primarily of calcium carbonate, i.e., aragonite. In many species, the coral skeletons possess internal growth banding, density banding, and/or external growth ridges, which record the growth rate of the colony. Coral colonies can live hundreds of years and therefore provide annual chronologies of growth rates over time in response to changing environmental

conditions. Coral sclerochronology encompasses the study of annual density band formation, historical growth records, and reconstruction of environmental records based on density band chronologies and skeletal chemistry of stable isotopes and trace elements.

### History

The term sclerochronology first appeared in the published literature in 1974 when Buddemeier et al. proposed: “Similar potentials have already been realized in the case of dendrochronology (Fritts et al., 1971); an analogous approach to the study of growth patterns in calcareous exoskeletons or shells could be designated sclerochronology” (Buddemeier et al., 1974). This was followed by a paper in 1976 entitled “Sclerochronology: a tool for interpreting past environments” (Hudson et al., 1976). Though the term sclerochronology may have arisen in the 1970s, the field of study has origins dating back to the nineteenth century when initial observations consisted of the apparently cyclical ridges on the external coral surface that were associated with periodic growth of the colony.

In 1898, referring to *Madrepora palmata* (*Acropora palmata*, Lamarck 1816), R. B. Whitfield remarked “Another feature worthy of mention is seen over all the larger spreading fronds in the form of broad undulations. These mark periods of growth, being thicker and thinner in substance, and are undoubtedly annual growths of the coral, . . .” (Whitfield, 1898); see Figure 1. In an effort to relate these “annual” growth patterns on the colony surface to environmental controls, Whitfield further speculated that they were a result of seasonal variations in water temperature. Vaughan (1915) later confirmed that these surface undulations were in agreement with annual growth rates for this species in the same locale.

Many of the early studies measured coral growth rates, though not directly from skeletal records, in order to address fundamental relationships between coral growth, environmental influences, and reef accretion (Finckh, 1904; Wood Jones, 1908; Mayor, 1918; Edmondson, 1929; Stephenson and Stephenson, 1933; Tamura and Hada, 1934). Much of this work, coupled with observations of cyclical skeletal ridges, led to the concept that corals may present useful chronometers of historical environmental, climatic, and even astronomical change (Wells, 1963; Runcorn, 1966; Shinn, 1966). The utility of corals as chronometers, suggested by these authors, was based on external growth ridges and directly measured growth rates; however, it was not based on internal variations of the skeletal architecture that produce annual density bands, which has come to be the most widely utilized characteristic in coral sclerochronology.

In 1933, the Chinese paleontologist, Ting-Ying H. Ma was the first to note that the internal skeletal architecture of Paleozoic corals (Silurian, Middle and Upper Devonian, and Lower Carboniferous) exhibited periodic variations in the size and densities of skeletal elements (dissepiments and tabulae), which appeared to reflect an annual cyclicity,

**Sclerochronology, Figure 1** Example of external growth ridges on *Acropora palmata* reported by R. B. Whitfield in 1898.

and further asserted that these variations were in response to seasonal climatic changes, in particular water temperature (Ma, 1933). Using modern corals, *Favia speciosa* from Japan, Ma found similar patterns characterized by variations in dissepiment thickness and spacing, which appeared as repeating bands within the skeleton (Ma, 1934a, b). Using these internal growth bands, Ma measured growth rates and deduced temporal relationships between growth rates and temperature, where higher growth rates were associated with warmer years and lower growth rates with cooler years. Ma (1937) also assessed corals from different regions (Pacific, Atlantic, and Indian Oceans) and found a spatial relationship between growth and temperature, where corals growing in regions of warmer temperature grew faster than that in regions of cooler temperature. Ma's research represents the first assessment of internal growth banding, a precursor to studies of annual density banding, as well as the spatial and temporal relationship between coral growth rates and water temperature.

A significant advancement in coral sclerochronology occurred in 1972 when Knutson et al. confirmed the annual nature of density banding using corals from Eniwetok Atoll, which were exposed to nuclear weapons testing fallout (Knutson et al., 1972). A combination of X-radiography and radioautography (Bonham, 1965), termed autoradiography by Knutson et al., was used to identify density banding and radioactivity banding, respectively, within medially sectioned skeletal slabs from the coral colonies. The number of density bands in between, and following, the radioactivity bands corresponded with the number of years between nuclear weapons detonations and the date of coral collections, thus providing a straightforward proof of the annual nature of coral density banding. Shortly thereafter, the annual nature of density banding was reconfirmed for different species and by radiometric analysis (Dodge and Thomson, 1974; Moore and Krishnaswami, 1974) and radiometric, staining, and direct measurement (Macintyre and Smith, 1974). Once the basic premise that coral skeletons possessed annual density bands had been established, the field of sclerochronology expanded quickly with novel approaches aimed at developing and understanding the measurement of linear extension rates, bulk

density, and calcification rates, the skeletal structural basis of density banding, environmental correlates of growth rates, coral growth ecology, and the impacts of climate change on coral growth rates.

Prior to the discovery of annual density banding, the chemical composition of coral skeletons had been analyzed for Ca and Sr (Thompson and Chow, 1955), Sr, Ca, and Ba (Bowen, 1956), Co, Ag, and U (Veeh and Turekian, 1968), C and O isotopes (Keith and Weber, 1965; Weber and Woodhead, 1970), Sr, U, Ba, Cu, B, Li, and Zn (Livingston and Thompson, 1971); however, geochemical analyses of coral skeletons as a chronological record had yet to be developed. Similarly, Ra, Th, and Pb were used as a radiometric confirmation of annual density banding, but it was not until the late 1970s when annual chronologies from density banding and geochemistry were used together to derive proxy environmental records (Goreau, 1977; Emiliani et al., 1978). Fairbanks and Dodge (1979) demonstrated annual periodicities in C and O isotopes, which illustrated the sclerochronological reliability and potential for proxy records of temperature stored within the chemical composition of the skeleton. Since this time, research into isotope fractionation, incorporation of trace elements, and the application to proxy reconstructions have rapidly expanded providing extensive contributions to the fields of paleoclimatology, ocean circulation, and climate change (Swart, 1983; Druffel, 1997; Gagan et al., 2000; Swart and Grottoli, 2003; Grottoli and Eakin, 2007).

Fluorescence of the coral skeleton was initially suggested as a recorder of coastal rainfall by P. J. Isdale (1984) (Boto and Isdale, 1985). Though the nature of these fluorescent bands has been brought into question as a possible artifact of skeletal density variations (Barnes et al., 2003; Barnes and Taylor, 2005), skeletal fluorescence (luminescence) has been reported to provide records of runoff (Isdale et al., 1998; Lough et al., 2002), precipitation (Fang and Chou, 1992), and wind speed (Nyberg, 2002), monsoon climate and upwelling (Tudhope et al., 1996), mortality (Hendy et al., 2003), El Niño Southern Oscillation teleconnections (Hendy et al., 2003), rainfall and river flow (Lough, 2007), and hurricane activity (Nyberg et al., 2007).

### Growth measurements from density banding

Coral samples for sclerochronology were originally collected as whole colonies; however, the currently preferred method is to collect cores (5–10 cm in diameter) using pneumatic or hydraulic drills (Figure 2) due to the minimal impact on coral colonies when cores are replaced with appropriate plugs. The cores are sectioned into 0.4–0.8-cm thick parallel-sided slabs oriented along the primary growth axis. The slabs are then planed to precise thickness for accurate density determination. Slabs are rinsed profusely after cutting and planing to remove all loose debris that can affect densitometry and geochemical sampling. Methods and quality of X-radiography will vary greatly based on the type of X-ray machine used; however, as a general rule, longer exposure times using slow speed

**Sclerochronology, Figure 2** Coring of a coral colony using a hydraulic drill to obtain a skeletal record of coral growth rates.

film with a small grain size will produce the highest quality X-radiographs. As an example, using an industrial X-ray film at a source to object distance of  $>1$  m and X-ray machine settings of 70 kVp, 15 mA, and exposure times of 5–10 s will provide good X-radiographs (Figure 3).

Density banding is revealed on X-radiographs of skeletal slabs and is apparent as alternating light (high-density) and dark (low-density) bands on the X-radiograph. A couplet of light and dark bands represents a single year's growth and is most often referred to in the singular form as an annual band. The annual nature of density banding allows three parameters of coral growth to be determined: (1) linear extension rate, (2) bulk skeletal density, and (3) calcification rate. Assessing all three growth parameters provides the most complete understanding of coral growth, and no one parameter is universally representative of the others (Dodge and Brass, 1984).

The annual extension rate is measured from the top of one high-density band to the top of the next high-density band and presented in units of cm/yr. The first extension rate measurements were collected on X-radiographic positive prints using dial calipers and following a linear transect normal to the density bands and along the axis of maximal growth; see review of early growth studies in Buddemeier and Kinzie (1976). X-radiograph densitometry (Buddemeier, 1974; Dodge and Thomson, 1974; Chalker et al., 1985) and gamma densitometry (Chalker and Barnes, 1990) provide  $xy$ -data of density and distance along the coral slab, which can also be used to determine

**Sclerochronology, Figure 3** X-radiographic positive print with annual density banding (dark bands = high-density, and light bands = low density) and a photograph of the coral slab.

extension rates based on distance from one density maxima (or minima) to the next density maxima (or minima). Annual values can also be derived from the combination of adjacent high-density and low-density bands. Density data can be delimited into high-density and low-density bands by the midpoint, or average value, between maxima and minima and by the zero crossing of the second derivative of the density data, which is the inflection point between bands. High-density and low-density data provide information about growth rates, which may vary independently on a seasonal basis.

Density measurements of coral skeletons are best described as the bulk density over the thickness of a coral slab, as opposed to the density of calcium carbonate skeleton. Density data is presented in units of  $\text{g/cm}^3$ . The density of coral skeletons has been measured by a variety of techniques, including X-radiograph densitometry (Buddemeier, 1974; Dodge and Thomson, 1974; Chalker et al., 1985), gamma densitometry (Barnes and Devereux, 1988; Chalker and Barnes, 1990), computerized tomography (Bosscher, 1993; Bessat and Buigues, 2001), buoyant weight technique (Dodge et al., 1984; Barnes and Devereux, 1988), weight and volume (Highsmith, 1979), and mercury displacement (Dustan, 1975).

X-radiograph densitometry, a common method of density determination, is based on the principle that when two materials (e.g., a coral sample and an aluminum standard) are X-rayed and the exposed film exhibits equal optical density for both materials, the density of the sample material can be calculated. Buddemeier (1974) obtained the mass absorption coefficients for both the sample and standard from tabulated values; however, this technique required the exact determination of the applied X-ray voltage and was further complicated by the assumption of an effective X-ray beam energy and the inhomogeneity of the sample and standard. Chalker et al. (1985) avoided such problems by using relative mass absorption coefficients. They determined the relative mass absorption coefficient of the standard and sample by slopes of curves fitted to data of sample thickness vs. densitometer output voltage. Dodge and Kohler (1985) adapted these methods to image processing, which replaces the densitometer output voltages with gray-scale pixel values (0–255), which are converted to relative optical density (ROD) values. The values are not measurements of true optic density (OD), which ranges from 0.0 to 4.0, because OD requires measurement of the incident light intensity before passing through the X-radiograph (Carlton and Adler, 1996).

Once extension rates and density have been measured, the calcification rate is calculated as the product of extension and density and is presented in units of  $\text{g/cm}^2/\text{yr}$ . The calcification rate is a measure of the addition of mass, for a give area, over time, with the three growth parameters related by the formula:

$$\text{Extension (cm/yr)} \times \text{density (g/cm}^3\text{)} = \\ \text{calcification (g/cm}^2\text{/yr)}.$$

## Skeletal basis of density banding

The construction and growth of coral skeleton is based on the formation of aragonite crystals, at sites of calcification, which are organized into fan-shaped structures called sclerodermites, and represent the building blocks of skeletal architecture (Wells, 1956). The formation of aragonite crystals exhibits a diel pattern, where well-organized and closely arranged needles are formed at night and loosely arranged needles are formed during the day (Barnes, 1970; Gladfelter, 1983). These diel patterns in skeletal accretion produce daily external growth ridges (Barnes, 1972), which have been used as evidence for variation in the number of days per year from the Middle Devonian to present (Wells, 1963). Though daily growth ridges represent a valuable trait for sclerochronology, they are substantively different than the skeletal variations responsible for X-ray revealed annual density banding.

Buddemeier (1974), in his X-radiographic studies of coral skeletons, determined that variations in organic content nor trace element levels were substantial enough to cause the density variations associated with banding and proposed two alternatives for density-band formation: (1) the orderliness in which aragonite needles are deposited, and (2) the variation in size and spacing of the skeletal elements. Barnes and Devereux (1988) presented terminology for categorizing the scale of skeletal variations referring to the organization of aragonite crystals or needles as “microarchitecture” and the organization of skeletal elements (e.g., dissepiments, septa, and thecae) as “meso-architecture.” Barnes and Devereux analyzed the density of coral skeleton (*Porites* sp.) by gamma-densitometry, buoyant weight, and powdered skeleton techniques and found that variations in microarchitecture were insufficient to account for density banding and further suggested that variations in the skeletal mesoarchitecture were responsible for density banding.

Skeletal structures reported to vary in conjunction with density bands include thickness and orientation of trabeculae (Buddemeier and Kinzie, 1975), dissepiment thickness (Macintyre and Smith, 1974; Emiliani et al., 1978), dissepiment and costae thickness (Dodge et al., 1992), and septa and columellae thickness (Helmle et al., 2002), and a general thickening of all skeletal elements (Barnes and Devereux, 1988). It is generally accepted that periodic thickening and/or coalescing of skeletal structures are responsible for density banding and also that the specific structures responsible for producing density bands vary between genera and species. The impact skeletal structures have on the attenuation an X-ray beam passing through a coral slab and the resulting density bands (or false bands) on the X-radiograph has been described by experimental, theoretical, and modeled approaches (Barnes et al., 1989; Barnes and Lough, 1990; Barnes and Taylor, 1993; Taylor et al., 1993; Le Tissier et al., 1994).

## Causes of density banding and correlates of coral growth

The environmental or endogenous causes of annual density banding have not been clearly identified. Common hypotheses include temperature, light, productivity, and reproduction. Annual reproductive cycles may cause a metabolic shift from growth to gamete productions, larval development, or tissue repair from spawning. Mendes and Woodley (2002) found *Montastraea annularis* corals from Jamaica, which underwent a bleaching event in 1995–1996, failed to produce a high-density band in 1996 and suggested this was due to the lack of gonad development and spawning in 1996. Alternative explanations for this event could include the bleaching stress, lack of photosynthetic energy contributions, or exceptionally high temperatures. Mendes (2004) conducted a controlled experiment considering temperature, light, and reproduction relative to density banding and concluded that reallocation of energy from growth (extension rate) to reproduction (gonad size) was the likely cause of high-density band formation in *M. annularis* from Jamaica, which occurs in late August to early October. It is important to consider that gonad size, temperature, and light were all at their highest levels during the period of high-density band onset. Characteristics of temperature, light, and spawning cycles generally correlate (Mendes, 2004; van Woesik et al., 2006), which makes it difficult to disentangle the true cause of density band formation.

Temperature and light are the two most commonly cited limiting controls on coral growth rates and therefore are likely to play a dominant role in controlling subannual growth rates responsible for density banding. Weber et al. (1975) and Highsmith (1979) attributed density banding primarily to temperature with high-density bands forming when temperatures were at their peak. Buddemeier (1974) demonstrated strong correlation between density banding and precipitation though he attributed this primarily to the influences of light availability. Klein and Loya (1991) cited temperature and light as combined factors controlling density band formation. Wellington and Glynn (1983) found that light was a better correlate with high-density band formation and further suggested that density banding may be controlled by combined effects of light, productivity, and reproduction. Varying with temperature and light, autotrophic (photosynthesis) and heterotrophic (feeding) energy contributions may control metabolic resources in a cyclical pattern, thus giving rise to annual density banding. Klein et al. (1993) reported that timing of density band formation varied by depth (3 m, 30 m, and 51 m) and attributed this observation to autotrophy/heterotrophy ratios. Temperature and light might also control density banding through the energetic contributions of photosynthesis, where  $P/R$  ratios may exceed a threshold for photosynthetic contributions during the summer temperature maximums and/or when light levels exceed a similar threshold.

Correlations between environmental parameters and coral growth records derived from density banding have

included extension rates alone, as well as complete growth assessment, including density and calcification. Correlations of coral growth with environmental variables include depth and light vs. extension (Hubbard and Scaturro, 1985; Huston, 1985; Logan and Tomascik, 1991; Bosscher and Meesters, 1993; Logan et al., 1994); light vs. extension, density, and calcification (Wellington and Glynn, 1983); temperature vs. extension (Jokiel and Coles, 1977; Dodge and Lang, 1983; Guzman and Tudhope, 1998); temperature vs. extension, density, and calcification (Highsmith, 1979; Lough and Barnes, 1997, 2000; Carricart-Ganivet, 2004; Worum et al., 2007; Cooper et al., 2008; Lough, 2008; De'ath et al., 2009); hydraulic energy vs. extension, density, and calcification (Scoffin et al., 1992); precipitation vs. extension (Buddemeier et al., 1974; Fang and Chou, 1992); nutrients vs. extension (Tomascik and Sander, 1985; Klein et al., 1993), and nutrients vs. extension, density, and calcification (Wellington and Glynn, 1983). Coral skeletal records have also been used to assess growth responses to anthropogenic perturbations such as crude oil and oil dispersants (Lewis, 1971; Knap et al., 1983) and runoff and coastal development impacts from turbidity, sedimentation, and sediment resuspension (Dodge et al., 1974; Loya, 1976; Dodge and Vaisnys, 1977; Barnes and Lough, 1999; Carricart-Ganivet and Merino, 2001; Torres, 2001).

Coral sclerochronology is not rooted in a mechanistic understanding of the growth-limiting controls over varying temporal and spatial scales and is therefore prone to errors associated with causation inferred from correlation. No single environmental parameter has been demonstrated to consistently and fully explain the annual variability in extension, density, or calcification, and it is likely that the limiting controls on coral growth are a combination of environmental influences that interact on daily to decadal periods over varying spatial scales. Effective sclerochronology aims to better identify these interactions for constrained time periods and a defined ranges of influence.

## Coral growth and climate change

Skeletal deposition of corals and ultimately coral growth rates are generally controlled by environmental and climatic conditions and the chemical composition of the surrounding water. With regard to recently rapid climate change, influences from rising sea surface temperatures and increasing atmospheric carbon dioxide levels have potentially affected coral growth over recent years. Increased carbon dioxide levels have lowered the pH of oceanic surface waters with resultant decreases in the aragonite saturation state (Gledhill et al., 2008), which has been hypothesized to cause decreases in calcification rates of corals and other calcifying organisms (Smith and Buddemeier, 1992; Kleypas et al., 1999). Increased sea surface temperatures are known to exert a positive influence upon coral growth rates (Weber et al., 1975), which

occurs both on spatial (Lough and Barnes, 2000) and temporal (Lough and Barnes, 1997) scales. However, coral growth is also negatively influenced by the metabolic effects of coral bleaching, which occurs above their thermal tolerance (Jokiel and Coles, 1977; Goreau and Macfarlane, 1990).

Records of coral growth consisting of extension, density, and calcification are predominantly short-term, decadal-scale, analyses used to assess site-specific growth ecology (Wellington and Glynn, 1983; Dodge and Brass, 1984; Lough and Barnes, 1992; Scoffin et al., 1992; Carricart-Ganivet et al., 2000; Carricart-Ganivet and Merino, 2001; Worum et al., 2007). Long-term coral growth records have generally been limited to extension rate measurements alone (Hudson et al., 1976, 1994; Dodge, 1981; Hudson, 1981; Dodge and Lang, 1983). Relatively few studies have measured all three parameters of growth for long-term, multidecadal to century-scale records. Lough and Barnes (1997) and Bessat and Buigues (2001) measured extension, density, and calcification over century-scale records and reported a positive relationship between sea surface temperature and calcification over the twentieth century. However, Lough (2008) reported recent declines in 5-year averaged calcification and extension between 1965 and 2005 despite increasing sea surface temperature over the same period. De'ath et al. (2009) analyzed ten multicentury growth records in combination with many shorter and more recent coral growth records (up to 328 colonies) and identified a 14% decline in calcification and 13% decline in extension since 1990. Recent declines in calcification have also been reported in two short-term studies (Cooper et al., 2008; Tanzil et al., 2009). The recent declines reported from coral records of extension and calcification suggest that the positive relationship between sea surface temperature and calcification over the twentieth century may not be holding up under current environmental conditions and that further analyses are necessary to assess the range of these reported declines in coral growth and the role aragonite saturation states may play in these declines.

## Summary

The field of coral sclerochronology arose from initial observations of external growth ridges, variations of internal skeletal structures, and apparent relationships between environmental conditions and coral growth. The confirmation of the annual nature of density banding led to modern methods of X-radiography, densitometry, and measurement of growth parameters: extension, density, and calcification. Coral sclerochronology has demonstrated its utility by advancing our understanding of coral growth ecology along with anthropogenic impacts and environmental influences on growth rates. The skeletal basis of density banding revealed on X-radiographs is well described; however, the fundamental cause of density banding has yet to be clearly defined. Based on decades of published research on coral growth rates and

environmental influences, it is clear that coral growth is not a fully controlled by a single environmental limiting factor, in contrast to the analogous field of dendrochronology. The value of coral sclerochronology lies in the ability of corals to store records of growth in their skeleton, over long periods of time, which reflect the sum total of environmental and climatic controls. The field of coral sclerochronology is continually advancing and provides unique records, throughout the tropical and sub-tropical oceans, of potential climatic/environmental change and anthropogenic influence.

## SEA LEVEL CHANGE AND ITS EFFECT ON REEF GROWTH

Hajime Kayanne, Chuki Hongo  
 University of Tokyo, Hongo, Tokyo, Japan

## Introduction

Over short timescales (minutes to months), sea level changes with tides, waves, atmospheric pressure, wind, and currents. Mean sea level (hereafter “sea level”) is the average level of the sea surface over a specific period (e.g., 1 year) after filtering out these short-term fluctuations. Sea level is determined from a reference level on land (e.g., a benchmark), and defined as an equipotential surface of the gravity field (i.e., the geoid).

At longer timescales (longer than a decade), sea level varies with changes in the volume of seawater and shape of the ocean basins. At timescales of  $10^3$  to  $10^5$  years

(e.g., over the Pleistocene or Quaternary periods), seawater volume is largely determined by the changing volume of ice sheets, and the associated redistribution of ice and water mass causes deformation of the earth surface and of the geoid. The former change is referred to as eustatic sea-level change, whereas the latter is referred to as glacial- and hydro-isostasy or geoidal change. At a timescale of  $10^2$  years (the timescale of global warming), the thermal expansion of seawater is the main factor that influences seawater volume, followed by melting of the ice sheets and ice caps (Bindoff et al., 2007); glacial- and hydro-isostasy or gravitational effect of water mass contribute a little to geographical variation in sea-level change at this timescale (Bamber et al., 2009).

Because sea level is a relative measure between the sea surface and land, vertical tectonic movements (i.e., uplift or submergence) also affect the relative position of the sea level; uplift and submergence of land result in a relative fall and rise, respectively.

Coral reefs are formed below sea level (generally below the low level of spring tide); thus, sea level determines the available accommodation space in which reefs can grow. Because coral reefs are formed in shallow water, the most important factor in the growth of hermatypic corals with symbiotic algae is light, which diminishes with depth. Consequently, corals thrive at water depths from below low tide water level to 20–30 m. The formation of coral reefs is controlled mainly by sea level, while long-term reef growth and geomorphological development are controlled by sea level change and its rate.

## Pleistocene sea level change and its effects on coral reefs

### Pleistocene sealevel change

Since the Pleistocene period, around 2.6 million years ago, sea level has fluctuated with amplitudes of 120–140 m in response to changes in the volume of ice sheets. A record of sea level change over this period can be found in the oxygen isotope ratio ( $^{18}\text{O}/^{16}\text{O}$ ) of foraminifera preserved in deep-sea sediment cores (Figure 1). Depleted isotope ratios indicate the inflow of meltwater from ice, and thus, high sea level. In contrast, heavy isotope ratios indicate the storage of water in ice sheets on land, and thus, low sea level. The amplitude and oscillation cycles of sea level can be reconstructed from continuous records preserved in sediment cores. Another proxy for sea level change during the Late Pleistocene are raised coral reef terraces.

Synchronous changes in sea level and the climate in general suggest conspicuous cycles that, since 800 kyr ago, changed their lengths from 40 kyr (kyr = 1,000 years) to 100 kyr (Figure 1). These cycles match the cycles of the orbital oscillation of the earth (axial tilt and orbital eccentricity), which result in temporal and spatial variations in insolation and that trigger and maintain steady cycles of climate change. Since 800 kyr B.P., warm interglacial periods have occurred at 630, 330, 200, and 125 kyr ago (Lambeck et al., 2002). During each glacial cycle, sea level rose rapidly from a low of –100 to –140 m (relative to present) to levels similar to the present sea level as

**Sea Level Change and Its Effect on Reef Growth, Figure 1** Proxy records of Pleistocene climate and sea level change (from Figure 3.1 in Hopley et al., 2007). (a) Marine oxygen isotope record derived from benthic foraminifera of deep-sea core ODP677, Oxygen isotope stages marked in *italics*. (b) (i) Reconstruction of sea level derived from uplifted coral reef terraces, Huon Peninsula, Papua New Guinea; (ii) oxygen isotope record from benthic foraminifera.

climate warmed, and then oscillated at cycles of 40 and 20 kyr during a fallback to the low levels.

The last cycle, from 140 kyr ago to the present, is well recorded in deep-sea sediment cores and by coral reef terraces. The cycle is divided into six marine isotope stages (MIS-6 to MIS-1; Figure 2c). MIS-6 is the penultimate glacial maximum, during which time sea level dropped to  $-125$  m at 133 kyr ago. During the last interglacial period (MIS-5e), sea level rose rapidly to around the present level or up to 5 m higher. This was followed by a series of oscillations between relatively cold stadials (MIS-5d and -5b), when sea level was 40–60 m lower than that of the present day, and warm interstadials (MIS-5c and 5a), when sea level was 20–30 m lower than that of today (Lambeck et al., 2002).

During MIS-4 and MIS-3, sea level fluctuated with an amplitude of 15 m between 40 and 70 m below the present level. During MIS-2, it dropped to a low of  $-125 \pm 5$  m during the Last Glacial Maximum.

### Effect of sea level change on coral reefs

During periods of low sea level (i.e., glacial times or cold stadials), coral reefs form on the edge of continental or island shelves at 100–140 m below the present sea level.

Moreover, the cold climate during these periods suppresses the formation of coral reefs, especially in subtropical regions. During periods of high sea level (i.e., interglacial times or warm interstadials), the rise in sea level provides space for reef formation on continental or island shelves, and reef formation is enhanced by the warm climate. Consequently, past coral reefs showed strong development during interglacial periods.

In tectonically active areas of continuous uplift, past coral reefs that formed during interglacial or interstadial periods have been uplifted above the present sea level (Huon Peninsula, New Guinea: Chappell, 1974; Chappell and Polach, 1991; Barbados: Mesolella et al., 1969, 1970; Vanuatu: Cabioch et al., 1998; Ryukyu Islands, Japan: Sasaki et al., 2004). Tectonic uplift generally occurs episodically: large seismic events typically occur at recurrence intervals of several hundred years with a displacement of up to several meters. However, at the timescale of sea level change ( $10^3$ – $10^4$  years), tectonic uplift can be regarded as temporally uniform. Thus, to use an analogy, tectonic uplift serves as a recording chart moving at constant speed, on which sea level is recorded like an oscillating pen-line on a chart (Mesolella et al., 1969). Therefore, regions with a high rate of tectonic uplift

**Sea Level Change and Its Effect on Reef Growth, Figure 2** Model of the formation of coral reef terraces and an atoll by tectonic uplift and subsidence superimposed upon Pleistocene sea level change. (a) Sea level change for the last 240 kyr. (b) Formation of coral reef terraces with a constant uplift rate of  $2 \text{ m kyr}^{-1}$ . (c) Formation of an atoll with a constant subsidence rate of  $0.2 \text{ m kyr}^{-1}$ .

preserve coral reef terraces that formed during small-amplitude fluctuations in sea level. In other words, uplifted coral reef terraces provide an accurate record of sea level change, assuming a uniform rate of uplift (assumed to be  $2.0 \text{ m kyr}^{-1}$  in Figure 2b).

In tectonically stable areas, in contrast, coral reefs that form during interglacial periods are overprinted by reef formation during subsequent interglacials. Returning to the above analogy, it is as if the recording chart has stopped moving and the pen begins to record on the same part of the chart, thereby obscuring the earlier record. In such a case, only the most recently formed reef (i.e., that which formed during the current postglacial period, since 19 kyr ago; see the next section) is preserved to form the present coral reef landform (e.g., Mauritius: Montaggioni and Faure, 1997; Mayotte: Camoin et al., 1997; Great Barrier Reef, Australia: Marshall and Davies, 1982). In areas of ongoing submergence, coral reefs build upward upon preceding reefs.

The Huon Peninsula, New Guinea, contains well-preserved coral reef facies that formed during interglacial periods. The reef that formed during the Last Interglacial has been uplifted to 330 m above the present sea level; reefs that formed during other interstadial periods are also exposed upon the peninsula (Chappell, 1974). The raised coral reefs consist of shallow reef-crest facies, dominated by robust branching (or corymbose types) corals of *Acropora humilis* that overlie deeper fore-reef facies dominated by massive corals. This facies change, from deeper to shallower reefs, reflects the process of reef formation “catching up” to the higher sea levels during interglacial periods.

**Sea Level Change and Its Effect on Reef Growth,**  
**Figure 3** Post-glacial sea level change for the past 20 kyr (from Figure 5 in Lambeck et al., 2002). The sea level curve shows ice-volume equivalent one based on isostatically adjusted sea-level data from different localities. MWP-1A refers to the timing of the meltwater pulse at 14 kyr ago. At the Younger Dryas (YD) at 12 kyr ago, sea-level rise may have momentarily halted.

Oceanic atolls form in environments of submergence combined with oscillations in sea level. During glacial periods, when sea level is low, coral reefs are exposed to the air and eroded to form a karst surface, which modifies the original reef landform. During periods of high sea level, coral reefs become reestablished over the previously exposed surface. In such cases, seismic profiles across and drill cores in atolls reveal multiple reef layers separated by solution unconformities. The uppermost unconformities of this type are observed at  $-5$  to  $-20$  m below the present sea level, representing the erosion of coral reefs that formed at 125 kyr ago, during the last interglacial period (Dickinson, 2004). Figure 2c shows schematic profiles across an oceanic atoll with a subsidence rate of  $0.2 \text{ m kyr}^{-1}$ .

## Postglacial sea level change and its effects on coral reefs

### Postglacial sea level change

Sea level reached its lowest level of  $-125 \pm 5$  m below the present level from 30 to 19 kyr ago (MIS-2 or the Last Glacial Maximum). Subsequently, with melting of the ice sheets, sea level rose at an average rate of  $10 \text{ m kyr}^{-1}$  ( $10 \text{ mm year}^{-1}$ ), attaining the present level by 7 kyr ago (Figure 3). However, the rise was not temporally uniform: a period of rapid sea-level rise occurred at 14.5 kyr B.P. as a result of rapid decay of the ice sheets, resulting in a rate of sea-level rise of  $40 \text{ mm year}^{-1}$  over a period of 500 years (total rise in sea level: 15 m). This episode is termed meltwater pulse 1A (MWP-1A). Similar such episodes occurred at 19 and 11.5 kyr (MWP-1B) (Fairbanks, 1989). At 12 kyr, in contrast, sea-level rise was interrupted and remained constant for about 1,000 years, corresponding to a cold period named the Younger Dryas.

Sea level curves show spatial variations due to the variable glacial- and hydro-isostatic response of the earth to the melting of ice and redistribution of water. For small islands located far from the ice sheets (i.e., islands in far-field regions), the curve largely traces the change in ice volume, as described above. In the mid-Pacific, however, a 1–2 m high sea stand was observed during the mid-Holocene (Mitrovica and Peltier, 1991). At large islands and along the continental coast in far-field regions, this mid-Holocene high stand is evident as a hydro-isostatic effect. In the intermediate-field region, near the former ice sheets, the magnitude of the postglacial rise in sea level was much smaller than the equivalent rise in ice volume, because of submergence of the crust that had formed a bulge around the ice sheet. For example, in the Caribbean Sea, the amount of postglacial sea-level rise was 115 m in Barbados (Fairbanks, 1989), and sea level has risen continuously to the present level at smaller average rates. The geographic differences between the Indo-Pacific Oceans and Caribbean Sea have resulted in contrasting histories of sea level change. In the Western Indian Ocean, sea level has never been higher than that of the present (Camoin et al., 1997, 2004).

### Effect of postglacial sea level change on coral reefs

Coral reefs grow upward to fill the available water space created by a rise in sea level. The different patterns of reef growth in response to postglacial change in sea level can be classified into keep-up, catch-up, and give-up styles (Davies et al., 1985; Neumann and Macintyre, 1985).

Keep-up reefs grow at a rate equal to sea level rise, thereby maintaining the upper reef surface close to the sea surface throughout its growth (Figure 4). Keep-up reefs consist entirely of shallow-water corals throughout their growth. In each case, a robust-branching (corymbose) form of *Acropora* is the main reef builder: *A. palmata* in the Caribbean Sea (Lighty et al., 1982) and *A. humilis*, *A. robusta*, and *A. danai* in Indo-Pacific reefs (Fairbanks, 1989; Bard et al., 1996; Camoin et al., 1997; Montaggioni et al., 1997). These corals grow in

water depths of less than 6 m (Lighty et al., 1982; Cabioch et al., 1999), with a vertical accumulation rate of less than  $6 \text{ m kyr}^{-1}$ .

Catch-up reefs begin to grow from a relatively deep site, finally catching up with sea level before or after sea level has stabilized. Catch-up reefs consist of shallow-water facies (robust-branching corals) underlain by deeper-water facies that generally consist of encrusting corals (e.g., *Echinopora gemmacea*, *Platygyra daedalea*, *Pachyseris rugosa*, and *Leptoria irregularis*), and bioclastic sand and gravel. There is little biogeographical variation in the species of robust-branching corals. In the Indian Ocean and Western and Central Pacific, the robust-branching corals in catch-up reefs consist of *A. digitifera*, *A. hyacinthus*, *A. cytherea*, *Pocillopora verrucosa*, *Goniastrea retiformis*, and *Favia stelligera*

**Sea Level Change and Its Effect on Reef Growth, Figure 4** Styles of reef growth in response to post-glacial sea level change (Based on Figure 3 in Neumann and Macintyre, 1985).

(e.g., Montaggioni and Faure, 1997; Cabioch et al., 1999; Kayanne et al., 2002; Hongo and Kayanne, 2009). In the East Pacific and Hawaiian Islands, such corals consist of *P. damicornis*, *P. meandrina*, and *Porites compressa* (Easton and Olson, 1976; Cortés et al., 1994; Grigg, 1998). The vertical accumulation rate of the deeper facies sometimes exceeds  $10 \text{ m kyr}^{-1}$ , reaching up to  $20 \text{ m kyr}^{-1}$ , but the rate decreases as the reef catches up with the sea surface and the corals change to shallow-facies species (Kayanne, 1992). Vertical accretion of the reef ceases once it has caught up with the sea surface, thereafter being replaced by lateral growth. Many coral reefs have kept pace with rising sea level for the past 11 kyr (Davies et al., 1985; Montaggioni, 1988).

Give-up reefs are those unable to catch up the rising sea level, eventually becoming deeply submerged and dying off. Give-up reefs are a common feature of many insular shelves in the eastern Caribbean (Macintyre, 1972) and the Great Barrier Reef (Harris and Davies, 1989). Barbados, in the Caribbean, is rimmed by three relict reefs consisting of *A. palmata* at  $-80$ ,  $-40$ , and  $-10 \text{ m}$  below the present sea level; these reefs yield ages of 11–18, 10–11, and 6–9 kyr, respectively (Fairbanks, 1989). A complex ridge system occurs along the shelf edge of the St. Croix. A shallow-water *A. palmata* reef flourished on the shelf edge off south coast of St. Croix 9 kyr ago, but eventually succumbed to stress caused by rising sea level (Macintyre, 1988).

**Sea Level Change and Its Effect on Reef Growth, Figure 5** Holocene history of reef formation and reef zonation. Based on Figure 1 in Kan (2007) with permission from Department of Geography, Tokyo Metropolitan University.

After the reef submerged by rapid rise in sea level, the new reef was formed at the landward position from the submerged reef (back-stepping). On the other hand, in tectonically active areas, as the reef uplifted episodically (in general accompanying with seismic activity), the new reef was formed seaward of the raised reef, and progradation occurred episodically rather than gradually (Kayanne et al., 1993).

A distinct reef zonation develops following the stabilization of sea level (Figure 5). Corals are characterized by a variety of growth forms whose distribution is related to gradients in environmental factors such as light, sediment, and wave energy. Wave energy is especially important in this regard (Chappell, 1980; Yamano et al., 2003; Hongo and Kayanne, 2009). For example, robust-branching corals are characteristic of settings with high wave energy. In the Caribbean, this corresponds to a zone of *A. palmata* (Lighty et al., 1982); in the Indo-Pacific: *A. humilis*, *A. robusta*, *A. digitifera*, and *P. verrucosa* (Cabioch et al., 1999). In settings with very high wave energy, corals are replaced by calcareous algae (Geister, 1977; Grossman and Fletcher, 2004). Indeed, an algal ridge is a prominent feature of many Indo-Pacific and Caribbean. Arborescent corals (e.g., *A. muricata*, *A. intermedia*, and *A. cervicornis*) grow in relatively sheltered reefs, and foliaceous and encrusting corals (e.g., *E. lamellose*, *P. rugosa*, and *L. irregularis*) are common in settings with low wave energy.

Reef islands are common features of atolls (Stoddart, 1969). In areas with frequent storms, reef islands generally contain gravel deposits on the windward side of the atoll. In storm-free areas, in contrast, gravels are not major component, and sand cays are developed on the atoll. It is likely that reef islands show temporally variable rates of accretion in response to environmental change (e.g., Holocene sea level change and ocean conditions). For example, sea-level fall over a period of 2,000–4,000 years may be necessary for a reef island in the Pacific (Buddemeier et al., 1975; Woodroffe et al., 1990; McLean and Woodroffe, 1994). Although reef islands are from areas in which sea level has fallen, similar reef islands are found in the Caribbean and Indian Ocean, where sea level rose or was stable during the formation of reef islands (Woodroffe et al., 1999; Kench et al., 2005).

## Conclusion

At timescales greater than  $10^3$  years, sea level change is the primary factor controlling the formation of coral reefs. Accordingly, coral reefs represent the most effective proxy in reconstructing the history of sea level change. For example, the most precise history of sea level change during the Late Pleistocene and postglacial period is attained from analyses of coral reef terraces and drill core recovered from modern reefs. However, such an approach is susceptible to circular reasoning in terms of assessing the response of coral reefs to sea level change, which itself is reconstructed based on the formation process of coral

reefs. To overcome this problem, it is important to obtain independent signatures of sea level change (e.g., peat; Toscano and Macintyre, 2003) and to evaluate the reliability of specific corals for sea level proxies.

## SEAGRASSES

Mark D. Merlin  
 University of Hawaii at Mānoa, Dean Hall, Honolulu,  
 Hawaii, USA

## Definitions

Seagrasses are monocotyledon flowering plants adapted to marine environments.

Seagrass beds or meadows are marine communities comprising seagrass species that provide habitat for many other organisms.

## Introduction

Seagrasses are the only botanical species whose ancestors recolonized the sea. This unusual group of vascular plants is generally defined as a diverse assemblage of angiosperm, monocotyledon plants found in brackish or more usually in marine waters of relatively shallow tropical and temperate regions of the world. These submerged flowering organisms complete their entire life cycle underwater producing oxygen as they photosynthesize radiant energy. Seagrasses are normally rooted in thick, often vast, productive beds or meadows. As salt-water plants, they influence the physical, chemical, and geological processes affecting coastal environments in which they live by filtering waters and dissipating wave energy. Seagrasses also anchor sediments and thus provide protection from erosion. In addition, they provide habitats and food resources for many invertebrates, fish, and avian species, as well as a few reptiles and mammals, including some endangered marine species. Unfortunately, today many seagrass beds have been severely degraded due to a variety of human activities. Protection of these communities is essential for the preservation of many marine species (Figure 1).

## Seagrass biology

Seagrass species have apparently evolved from dissimilar groups of freshwater plants; indeed, some seagrass species are closer in their evolutionary relationship to certain freshwater plants than they are to other seagrasses (Waycott et al., 2006). Although some water plant species can be found in marine habitats with low to moderate salinity, the assemblage of plant species defined as seagrasses occur only in oceanic water bodies with high salinity. These species do not require contact with the atmosphere, and their sexual reproductive cycle, including flowering and pollination, is completed under water. Particular adaptations of seagrasses to a life submerged in saltwater include an efficient ability to incorporate inorganic carbon from ocean water. They are able to obtain nutrients required for growth in some cases by direct uptake through their roots (similar to the process used by terrestrial plants), or in many situations, through their leaves from the water column itself. However, because sea floor sediment is typically deficient or devoid of oxygen, the underground parts of seagrass plants commonly obtain oxygen via their leaves by way of a system of air-filled channels that develop within their living tissue. Another important adaptation common to most seagrasses is their strap-like leaves (den Hartog, 1970), which allows these plants to flourish in aquatic environments that are heavily affected by the flows of tides and waves. Among seagrasses, pollen dispersal to female flowers,

typically aided by wind or insects in land plants, occurs via water currents (Borum et al., 2004).

## Seagrass research

Early research involving seagrasses focused on taxonomic comparisons of their superficial morphology with that of other plant groups and only relatively little attention was directed toward other botanical or human use aspects of these plants. The study of additional scientific and resource management aspects of seagrasses accelerated in the second half of the twentieth century; one publication in the late 1970s (Bridges et al., 1978) cited more than 1400 references from sources worldwide, and many, more recent studies of seagrasses have been undertaken during the past few decades (e.g., see Green and Short, 2003; Borum et al., 2004; Larkan et al., 2006; Heck et al., 2008).

## Seagrass taxonomy

Seagrasses are not true species of grass which all belong to the family Poaceae. In fact, seagrasses as a whole are best referred to as an ecological group rather than a taxonomic group. There is still no officially recognized classification system that completely describes the recorded genera of "true seagrasses." This situation can be explained by the polyphyletic nature of seagrasses, as well as the lengthy debate over placement of the individual genera into respective families and the lack of an accepted scientific definition of "seagrass." Although the quantity and biological classification of seagrass species is still disputed, it has generally been assumed that there are approximately 50–60 species of these marine flowering plants (Duarte, 2008; Hogarth, 2007; Hughes et al., 2009), belonging to 12 genera in four families. These include species in the following genera and families: *Posidonia* in the family Posidoniaceae; *Zostera*, *Heterozostera*, and *Phyllospadix* in the family Zosteraceae; *Enhalus*, *Halophila*, and *Thalassia* in the family Hydrocharitaceae; and *Amphibolis*, *Cymodocea*, *Halodule*, *Syringodium*, and *Thalassodendron* in the family Cymodoceaceae (according to Duarte (2008), over 50% of the seagrass species belong to *Halophila*, *Zostera*, and *Posidonia*; see Kuo and den Hartog, 2001 for short descriptions of all seagrass species recorded as of 2006). Other, recent phylogenetic research suggests that seagrass species can be further divided into six families: Cymodoceaceae, Hydrocharitaceae, Posidoniaceae, Ruppiaceae, Zannichelliaceae, and Zosteraceae (Waycott et al., 2006). However, even this taxonomic perspective is debatable since species belonging to the genera of *Ruppia* and *Zanichella* are able to complete their life cycles beyond marine waters (Larkum et al., 2006). Furthermore, some recent authors continue to refer to Potamogetonaceae as one of the seagrass families (e.g., Allen, 2003; Hogarth, 2007; Duarte, 2008).

## Seagrass biogeography

Seagrass species vary in the size of their leaves from more than 4 m long, as occurs in the strap-like blades of *Zostera caulescens* (eelgrass) in the Sea of Japan, to only 2–3 cm

in the rounded blades of *Halophila decipiens* (sea vine) in relatively deep tropical marine areas adjacent to Brazil. Seagrasses of one or sometimes multiple species often form extensive beds or meadows over shallow, unconsolidated sediments on all continental shelves except those of Antarctica, as well as on inshore environments of many oceanic islands of the world. For example, huge underwater seagrass beds occur along sections of the coasts of Australia, Alaska, southern Europe, India, east Africa, the islands of the Caribbean, and other places around the globe. The maximum water depth in which these salt-water plants are known to occur is ~90 m (Duarte, 1991). They can be found in both temperate and tropical marine environments, frequently growing near to and associated environmentally with coral reefs, mangroves, salt marshes, bivalve reefs, and other saline aquatic habitats. Seagrass beds can be either monospecific, comprising only a single species, such as *Zostera marina* in parts of the North Atlantic, or multispecific, where various species coexist, such as in tropical marine environments like the Philippines where up to 13 species are known to occur. The highest diversity of seagrasses in the world exists in Australia, which harbors over half of the world's species and contains the most widespread seagrass beds found anywhere (Butler and Jernakoff, 1999). New records of seagrasses are still being established, and in at least one case these records have expanded the known biogeographical distribution of some species. For example, until recently, the only seagrass species recorded in the Hawaiian Islands was the endemic *Halophila hawaiiiana* (Doty and Stone, 1966); however, we now know that a close relative, the very widespread seagrass species *Halophila decipiens*, also occurs in the Hawaiian Islands, where it was first recorded from Midway Atoll, and is now known from at least three locations spanning the archipelago (McDermid et al., 2002).

### The geomorphological role of seagrasses

Seagrasses play a role in helping create their own habitat, and thus they have been referred to as “ecosystem engineers” (Wright and Jones, 2006; Coleman and Williams, 2002). For example, their leaves reduce the speed of ocean currents which enhances sedimentary processes, and the roots and rhizome of seagrasses aid in the stabilization of the seabed; they literally hold or bond reefs together. In addition, seagrass beds improve water quality by stabilizing loose sediment and filtering some pollutants out of the water column. If seagrass beds were not in place, widespread marine areas in the world would have environments with unstable, shifting sand and mud. A recent modeling study by the United Nations Environmental Program, based on data collected from the effects of the huge 2004 Indian Ocean Tsunami, suggests that seagrasses provide the significant beneficial effect of absorbing wave energy and can thus reduce physical and biological damage from such a potentially devastating natural hazard (Chatenoux and Peduzzi, 2005).

### The ecological roles of seagrasses

Seagrasses provide a large number of vital ecological services to the marine habitats in which they are “foundation species” (e.g., Costanza et al., 1997; Hemminga and Duarte, 2000; Conservation International, 2008). Their significance for associated species is based primarily on the protective cover they provide by means of their three-dimensional configuration in the water column, as well as their extremely high rate of primary production (e.g., Virnstein, 1982; Phillips, 1992; Heck et al., 2008). Consequently, seagrasses supply inshore habitat with many ecosystem goods and services, such as nurseries for finfish, shellfish, and crustaceans; protection of biota from wave damage; production of oxygen; and shelter against coastal erosion. Generally, seagrass beds can be characterized as among the most productive natural communities in the world serving as major suppliers to the marine food web. Thousands of plants, animals, and other organisms live among the seagrasses in a multifaceted and delicate ecological environment. For example, sea turtles and sea cows (dugong and manatees) graze upon seagrass species, and numerous kinds of worms, snails, shrimps, crabs, and small fish live their whole lives within seagrass beds. In addition, many marine fish important to fishermen depend upon seagrass communities during some periods of their lives, and bigger fish and seabirds also come to these beds to eat the smaller animals. Although the role of seagrass (as well as mangrove) habitats as nurseries for coral reef fish species has long been debated, a study of the use of seagrass habitats by juvenile coral reef fish using visual census surveys at four islands along the East African coast of Tanzania and at the island of Grande Comoros in the Comoros archipelago indicates that areas with seagrass beds had a positive influence on the adult concentration of several reef fish species on adjoining coral reefs (Dorenbosch et al., 2005:63).

### Conservation issues affecting seagrasses

Seagrass beds can extend into deep waters, and those that still cover large areas today are typical of marine coastal environments that have not suffered from significant human impact. Because of the amount of light that seagrasses require, the depths in which they can survive are limited by water clarity, and because these marine plant species are generally perennial organisms, they develop over time into integrated, often highly diverse, biological communities. Therefore, seagrasses are prime indicators of the degree of anthropogenic disturbance in marine habitats, and thus they are useful for periodic ecological observation and the implementation of effective management policies. Even though a number of scientists and some concerned citizens recognize that healthy seagrass beds are of great value both ecologically and economically, a large number of their habitats in many regions of the world have been totally ruined or are being degraded rapidly by a multitude of human activities in the form of nutrient loading, siltation, and mechanical

**Seagrasses, Figure 1** *Enhalus acoroides* (L.f.) Royle [family: Hydrocharitaceae] shown here growing in the marine environment of Yap where it is one of seven seagrass species recorded from this area in Micronesia (photo: Mark D. Merlin).

disturbance (e.g., Short, 1987; Shepard et al., 1989; Short and Wyllie-Escheverria, 1996; Cardoso et al., 2004; Orth et al., 2006). Runoff of nutrients and sediments resulting from human activities on land are most likely the main overall threat to the existence and health of seagrass beds worldwide. Because of the relatively high light requirements of seagrass species, they are quite susceptible to the effects of nutrient and sediment loading on water clarity. Seagrass beds are also damaged directly by inappropriate boating activities, dredge-and-fill activities, and harmful commercial fishing practices. For example, the seagrass beds of Florida's coastal areas were reduced in aerial extent by about 60%, from approximately 5 million acres to 2 million acres, during the second half of the twentieth century (Figure 2), mainly by dredge-and-fill projects and reduced water quality (Florida Fish and Wildlife Conservation Commission, 2007). Global climate change that can result in rising sea level and the production of more frequent severe storms could and may already be having

**Seagrasses, Figure 2** Loss of seagrasses in Florida (1950–2000) is shown in relationship to the increasing human population in the State of Florida. Source: Florida Fish and Wildlife Conservation Commission. 2007. *Florida's Seagrasses*. Florida St. Petersburg, FL: Fish and Wildlife Research Institute, a Public Brochure.

impact on the range and vigor of seagrasses (Short and Neckles, 1999). Furthermore, seagrasses are the main food or are associated in other ways with a number of threatened and endangered species (e.g., see Hughes et al., 2009; Preen and Marsh, 1995); these include species such as the Green sea turtle (*Chelonia mydas*), fan mussel (*Pinna nobilis*), dwarf seahorse (*Hippocampus zosterae*), and dugong (*Dugong dugon*). Indeed, green sea turtles as well as dugongs and manatees (*Trichechus* spp.) are recognized as appealing species of significant public interest, and therefore the reduction and degradation of their necessary seagrass environment is a tragedy for these and many other species. Unfortunately, seagrasses worldwide are generally receiving modest protection even though there are numerous pressures on their various coastal habitats (Green and Short, 2003). Scientists agree that there is a strong need for competent monitoring and management strategies for many, if not most, seagrass species and their homes on coral reefs and other environments (e.g., see Duarte, 2002; Green and Short, 2003; Borum et al., 2004; Hughes et al., 2009). Furthermore, a significant increase in public awareness through communication and education regarding the important ecological and economic roles of seagrass communities is strongly needed to enlighten and stimulate effective management of these crucial coastal seagrass beds and the species that inhabit them (Duarte et al., 2008).

## Summary

Seagrasses are unusual, important, and underappreciated species that inhabit coral reefs and many other marine habitats. Extensive, naturally occurring seagrass beds or meadows provide key ecological and economic resources

for many coastal ecosystems worldwide. Even though there are still widespread seagrass beds on all of the world's continents except Antarctica, seagrass beds and the species they harbor have been reduced in size or completely destroyed in many areas. Human population continues to expand and become increasingly urbanized, with more and more people residing disproportionately in the world's coastal regions. Consequently, an increase in scientific study, effective resource management, and a major rise in public awareness of the environmental importance of seagrasses as coastal resources and vital habitats are more important than ever.

## SEA-LEVEL INDICATORS

Scott Smithers  
 James Cook University, Townsville, QLD, Australia

### Definition

*Sea level* is the local height of the ocean's surface, usually measured to a datum referenced to a tidal position established from a record in which high-frequency motions such as wind waves and periodic changes (e.g., due to the tides) have been averaged out. Local sea level fluctuates regularly with tides and irregularly in response to factors including wind and currents, water temperatures and salinities, and atmospheric pressure.

*Relative sea level* is the elevation of the sea surface relative to the land at a given location. Global or eustatic sea-level fluctuations occur as the volume of water in the earth's oceans changes when ice caps and glaciers grow or melt, or as large-scale changes in the configuration of ocean basins and continental margins occur through plate tectonics. There are also regional and local isostatic processes that produce spatially different patterns of relative sea-level change, including thermal expansion of surface waters, changes in meltwater load, crustal adjustment of areas directly or indirectly affected by ice on- and off-loading (see *Glacio-Hydro Isostasy*), coastal uplift or subsidence due to tectonic processes (see *Earthquakes and Emergence or Submergence of Coral Reefs*), and subsidence due to aquifer depletion or sediment compaction.

*Sea-level indicators* are used to determine relative sea-level changes at a location. Locating a sea-level indicator and determining its age and elevation relative to its modern counterpart can establish relative sea-level change. Sea-level indicators on coral reefs include a range of biological, geomorphological, sedimentological, and chemical features that provide information on the position of the sea surface at the time that they lived or were formed. They usually comprise features with a known relationship to a tidal position or datum.

### Introduction

Coral reefs are best developed in warm, clear tropical waters less than 30–50 m deep, where photosymbiotic organisms can access abundant energy provided by the

tropical sun (Falkowski et al., 1990) (see *Corals – Environmental Controls on Growth*). The restriction of vigorous reef growth to shallow depths is well known, and at the broadest level coral reefs at elevations and depths where they no longer survive have been used to determine larger longer-term sea-level changes, like those of the Quaternary (Bloom et al., 1974; Chappell, 1974; Cabioch and Ayliffe, 2001) (see *Emerged Reefs; Barbados; Huon Peninsula, P. N. G.; Submerged Reefs*).

A reef's shape can suggest an approximate depth, allowing the sea-level signal derived from whole reefs to be refined further (Adey, 1978). However, the most precise estimates of past sea-level position are established from the vertical zonation with respect to sea level of: (a) the range of plants or animals that live on and construct coral reefs and (b) the range of physical and chemical processes that may leave datable sedimentary or erosional signatures (Davies and Montaggioni, 1985; Hopley, 1986b) (see *Geomorphic Zonation*). Accordingly, coral reefs are recognized as valuable repositories of sea-level information, and sea-level studies from coral reefs have flourished in recent decades.

### Key attributes of useful sea-level indicators

Sea-level indicators on coral reefs are either *finite* (syn: *diagnostic* or *indicative*) or *directional*. Finite sea-level indicators have a definite relationship with the sea surface, whereas directional sea-level indicators only document whether sea level was above or below the indicator at the time of its formation (Chappell et al., 1983; Davies and Montaggioni, 1985). The growth or formation of finite sea-level indicators is usually restricted to a specific intertidal, shallow subtidal, or possibly peritidal depth range, and a quantitative relationship between the sea surface and the indicator can be established. This relationship is referred to as the "indicative meaning," which for a particular indicator in its local environment may have an elevational range quantified and reduced to a datum expressed relative to a tide level (e.g., mean low water springs (MLWS)) with an associated error range (van de Plassche, 1986). Finite indicators are normally constrained within a narrow (<2 m) depth range, and are usually formed within 5 m of the sea surface (Davies and Montaggioni, 1985). Finite indicators are preferred for high-resolution sea-level studies, but are rarely formed during rapid transgressions or regressions (see *Postglacial Transgression*).

Excellent reviews of sea-level indicators are provided by Davies and Montaggioni (1985), van der Plassche (1986), and Pirazzoli (1991). These and other studies conclude that the key attributes of useful sea-level indicators are:

1. A narrow vertical depth range
2. A reproducible elevation
3. Good geological preservation
4. Capacity to be accurately dated

The major sea-level indicators used to establish sea-level histories on coral reefs satisfy the above criteria, and are described below.

### Main sea-level indicators on reefs

#### Coral reefs and corals

Sea level constrains coral reef growth and significantly influences coral reef morphology; continued upward growth is limited by emergence, and the depth below sea level at which reef growth can occur is limited by light – calcification by reef-building organisms is most efficient in the upper euphotic zone, which is normally within 50 m of the surface (Falkowski et al., 1990) (see *Corals – Environmental Controls on Growth*). Although individual corals may survive in deeper waters, they rarely develop reefs because photosynthetically active radiation is limited, reducing calcium carbonate production and accumulation to below rates of removal. Actively growing coral reefs are thus confined to a narrow (~50 m) depth window near the sea surface that makes them excellent gross indicators of sea-level position. The upper 30 m, in which most of the world's coral reefs grow, represents <1% of the mean 3,729 m depth of the world's oceans (Hopley et al., 2007).

Coral and coral reef cores provide many sea-level data. With few exceptions (identified below), they must be considered relatively imprecise directional sea-level indicators as the depth at which a coral grew can rarely be precisely determined, and thus the indicative range may be >30 m. However, corals and many other reef materials have good preservation potential and can be accurately dated using radiocarbon and uranium-series methods (see *Radiocarbon ( $^{14}\text{C}$ ): Dating and Corals; Uranium Series Dating*). As a result, sea-level data from coral reefs generally have relatively large elevation but small age-error terms.

Coral reefs have made a particularly important contribution to the knowledge of Quaternary sea-level

fluctuations. Dating of emergent reefs at relatively stable mid-plate oceanic islands (e.g., Oahu, Hawaii) and at stable continental margins (e.g., Western Australia) showed that sea level during the last interglacial (LIG) was ~6 m above present (Stirling et al., 1995) (see *Emerged Reefs*). Recent work from other Caribbean and Indo-Pacific reefs suggests the LIG peak was 2–10 m higher than at present (Chen et al., 1991; Israelson and Wohlfarth, 1999). Relict coral reefs drowned by rapidly rising postglacial sea levels are also known from several areas (“give-up” reefs of Neumann and Macintyre (1985); see *Reef Classification, Response to Sea Level Rise*) that provide valuable sea-level data. For example, drowned reefs with shallow-water features have been described and dated off the west coast of Barbados (e.g., Macintyre et al., 1991) and southeast Florida (Lighty et al., 1978) in the Atlantic (see *Barbados*), and similar features have been described on the Great Barrier Reef (GBR) shelf edge (Harris and Davies, 1989; Hopley et al., 1997). The shallow-water features and facies on many of these reefs have been interpreted as evidence of relatively slowly rising or briefly stable sea-level periods during the postglacial transgression (see *Postglacial Transgression*), with the termination of reef growth attributed to rapid submergence associated with meltwater pulses (see *Meltwater Pulses*) or water quality or temperature constraints (Macintyre, 1972; Adey et al., 1977; Lighty et al., 1978; Macintyre et al., 1991) (see *Submerged Reefs*). Ironically, the best records of past sea-level change are not preserved in tectonically stable areas because evidence can be eroded, reworked, or buried by subsequent sea-level oscillations. Emergent reefs formed as fringing reefs (see *Fringing Reefs*; Figure 1a) on rapidly uplifting coasts yield the best evidence for Quaternary sea-level changes, as whole reef geometry, biological and geomorphological zonation (see *Geomorphic Zonation*), and sediment facies can be observed and interpreted for accurate paleo-sea-level

**Sea-level Indicators, Figure 1** (a) Uplifted reef terrace, Sohona, Bouganville, Papua New Guinea; (b) emergent mid-Holocene reef at Kirimati, Kiribati, showing intact in situ *Acropora* still in growth position, approximately 1 m above modern equivalents.

determination (Sasaki et al., 2004). Recent improvements in technology have greatly enhanced access to and detailed observations of submerged reefs in areas of tectonic subsidence (Faichney et al., 2009) and deep submarine slopes (see *AuVs (RoVs)*; *Swathe Mapping*). These hitherto largely inaccessible reefs will no doubt give up valuable sea-level information in future years.

Emergent reefs provide access to a range of dateable materials, some of which may be cross-checked with other evidence to improve the accuracy of reef growth and sea-level chronologies (Figure 1b). Fossil corals from reef terraces have been radiometrically dated and compared with the deep-sea record of ice-volume changes to deduce large-scale sea-level change, but the details of the reef terrace and deep-sea sea-level interpretations are less perfectly accordant beyond the limit of radiocarbon dating (e.g., ~40,000 years; Cabioch and Ayliffe, 2001).

Relative sea level at any location is a function of vertical movements of the land and changes in the absolute elevation of the sea. Where tectonic uplift and sea-level rise rates are comparable, *relative* sea level stability may be encountered and reef flats may form. The same eustatic sea-level change will produce dissimilar reef terrace sequences in areas with different tectonic histories. However, if long-term rates of uplift or subsidence are known and reef terraces age can be established, the sea level at the time of reef formation can be calculated. The coordinated analysis of sea-level histories reconstructed from reef terraces at locations with different tectonic heritages has enormously progressed knowledge of the amplitude and timing of Quaternary sea levels.

Where in situ coral immediately overlies an unconformity, reef growth over transgressive surfaces is indicated by paleosols, diagenetic alterations (see *Diagenesis*), and calcrete stringers (see *Calcrete/Caliche*) (e.g., Hopley, 1982; Webster and Davies, 2003). This depositional sequence is a firm directional sea-level indicator, although verifying the in situ condition and the time lag between inundation and coral growth is challenging. Sedimentary facies and/or species assemblages (biofacies) within the structure of many reefs have been interpreted as diagnostic of reef initiation, catch-up, and growth at sea level (e.g., Neumann and MacIntyre, 1985; Montaggioni and Faure, 1997); some researchers have described subfacies and biofacies within these larger divisions that may track sea level even more precisely (e.g., Montaggioni et al., 1997; Webster et al., 2009).

Sea level and sedimentary style are plausibly linked; for example, sand aprons prograde leeward of many GBR reef flats, with subtidal sands fining upward but intertidal sands coarsening upward (Davies, 1983). If preserved, these sequences – and their juxtaposition – may comprise a directional sea-level indicator, or possibly a coarse but finite sea-level indicator if reef flat corals are also identified (Davies and Montaggioni, 1985). The vertical distribution of reef taxa along depth-related environmental gradients is similarly credible, with many descriptions

and explanatory models for the zonation of coral reef assemblages available (e.g., Wells, 1954; Done, 1983; Davies and Montaggioni, 1985). However, these distributions are influenced by both physical and biological interactions, which may be very complex and variable between locations and through time, and thus reef assemblages have not been widely used as finite sea-level indicators as the reproducibility and precision with which they record sea level is generally low.

The best-known coral species used as a sea-level indicator is *Acropora palmata* (see *Acropora*) – a shallow-water coral normally restricted to within 5 m of the sea surface. *Acropora palmata* grows in the Caribbean where it forms monospecific communities. Its presence has been used to define when a reef is in shallow water, and to identify keep-up reefs in which vertical accretion tracked sea-level rise (Lighty et al., 1982; Toscano and Macintyre, 2003). Assemblages of corals and coralline algae have been argued as depth definitive (Montaggioni and Faure, 1997; Montaggioni et al., 1997), but as discussed above the precision of these relationships is generally low and the interpretation controversial (Blanchon, 1998). Corals are, however, zonally distributed across environmental gradients including depth and wave energy, and various coral morphotypes are stratified across these zones (Chappell, 1980). The Atlantic-Caribbean massive coral *Montastrea annularis* adopts a platy morphology at depth where light is limited (Woodroffe, 2003), for example, and *Pocillopora damnicornis* colonies are more robust in shallower higher wave-energy habitats (Mass and Genin, 2008). Where the steepness of these gradients can be understood and calibrated reliably to depth, morphotypic variation in corals may be used to reconstruct sea-level histories. This is likely to be most fruitful in the Caribbean where the Holocene sea-level history has promoted the development of keep-up reefs dominated by framework structure. Where detrital sediments dominate the internal structure of reefs, like the GBR (Hopley et al., 2007), reconstructing sea levels by comparing extant taxa and/or morphotypic depth distributions with those recovered in cores is difficult. The use of coral or coral reef material as sea-level indicators in high-energy or storm-prone settings is problematic as material can be transported above growth position and sea level overestimated without careful verification of in situ status.

Algal rims are distinctive reef crest features on many mid-Pacific atolls and some higher-energy Atlantic reefs (e.g., Nunn, 1993), and a coralline algal ridge, particularly of the pink algae *Porolithon*, indicates reef growth near the sea surface (near MLWS, but higher in higher-energy settings (e.g., Woodroffe et al., 2004)) (Figure 2) (see *Algal Rims*; *Algae, Coralline*). Thick algal encrustations are normally restricted to within 4–6 m of the sea surface, but distribution above and below sea level can differ with wave energy. Algae species and morphology systematically vary with depth and wave exposure (Davies and Montaggioni, 1985). Adey (1986), reviewed coralline algae occurrence, and potential use as sea-level indicators,

**Sea-level Indicators, Figure 2** Algal rim at outer edge of reef flat at South Island, Cocos (Keeling) Islands, Indian Ocean.

suggesting that for several species with well-defined ecological niches precision of  $\pm 10$  cm may be realized.

### Microatolls

Microatolls are intertidal corals with dead, relatively flat upper surfaces surrounded by an annular rim of living coral (Figure 3a) (see *Microatoll*). They form when upward coral growth is constrained by prolonged exposure near low water, but polyps on the sides remain alive and continue to grow laterally (Scoffin and Stoddart, 1978; Woodroffe and McLean, 1990). Microatolls are amongst the most precise, geologically persistent, and useful finite sea-level indicators found on coral reefs (Davies and Montaggioni, 1985). Their flat upper surfaces confirm that the coral, and the reefs they overlie, have vertically accreted to the intertidal, and they have been widely used as sea-level indicators because the elevation of their upper surfaces and the sea surface closely correspond.

The exact elevation at which upward coral growth is restricted and a microatoll develops varies between species, and with exposure to wavelet wetting, diurnal and seasonal tidal patterns, and a variety of other factors. However, a high degree of reproducibility of elevation is usually observed between microatolls within the same “field.” On the mesotidal central GBR, the tops of neighboring *Porites* microatolls within a field were within  $\pm 10$  cm (Chappell et al., 1983), and on microtidal mid-ocean reefs microatoll tops in a single habitat varied even less ( $\pm 5$  cm) (Smithers and Woodroffe, 2000). Microatolls on the GBR in habitats freely connected to open water – where the rise and fall of the tide is unimpeded by reef topography – are elevated around MLWS (Scoffin and Stoddart, 1978). At the microtidal Cocos Keeling Islands, most open water microatolls grow above this tidal datum,

**Sea-level Indicators, Figure 3** (a) Living *Porites* microatoll, on reef flat at Poruma, Torres Strait; (b) Fossil *Porites* microatoll >6,000 years old, Iris Point, Great Barrier Reef (GBR), Australia.

with the modal elevation approximately halfway between MLWS and mean low water neaps (MLWN) (Smithers and Woodroffe, 2000). This difference probably reflects the proportionally larger influence of waves on modifying the tidal levels that restrict upward coral growth at Cocos and other mid-ocean microtidal reefs; microatolls at the Cook Islands are also constrained midway between MLWS and MLWN (Goodwin and Harvey, 2008).

Microatolls may grow to several meters in diameter and vary from centimeters to meters in thickness, but most are 1–2 m across and less than 0.5 m high. Both massive and branching corals form microatolls; however, those developed by massive corals are more common and better preserved. The excellent preservation potential of microatolls is demonstrated by the common occurrence of fossil microatolls of mid-late Holocene age on Indo-Pacific reef flats (Figure 3b) (see references below); they are rare in the Atlantic-Caribbean as sea level there has only recently been reached. Modern microatolls often grow in sight of fossil microatolls, and their elevations can be compared directly and surveyed to a tidal datum. Fossil microatolls are well suited for both radiocarbon and uranium-series dating, and thus histories of sea-level change can be established. Chappell et al. (1983) used this approach to determine late Holocene sea-level change on the central GBR, and it has also been applied to establish sea-level histories elsewhere in the Pacific (e.g., Pirazzoli and Montaggioni, 1986; Pirazzoli et al., 1987; Goodwin and Harvey, 2008) and Indian Oceans (e.g., Woodroffe et al., 1990; Kench et al., 2009).

Microatolls can also be used to reconstruct interannual changes in sea level with high precision. Microtopographic undulations over the upper surfaces of well-preserved microatolls track interannual variations in the elevation of the confining water level, within the limits of coral growth (Woodroffe and McLean, 1990; Smithers and Woodroffe, 2001) (see *Microatolls* for detailed description). Annual growth bands are revealed within microatoll skeletons when slices taken through the growth axis are either X-rayed or illuminated with UVB light, and these define a chronology for the upper limit to coral growth for each band (and by inference the height of the confining water level) (see *Sclerochronology*). Back-counting bands (years) from the living annulus at the time of sampling enables sea-level records to be reconstructed that extend back over the coral's lifetime. For a colony a meter in diameter, this would be around 50 years, but may include several centuries for larger specimens several meters across. When microatolls with overlapping life spans are found, their records can be cross-correlated and combined to extend the record. This approach can also be applied to well-preserved and radiometrically dated fossil microatolls of overlapping age (Yu et al., 2009).

Microatolls are excellent sea-level indicators. However, several issues need consideration when they are used. Verification is required that they: (a) are microatolls and not “pseudomorphs” with planar tops caused by erosion (confirmed by examining a colony's internal

structure), (b) are in situ and have been undisturbed by storms or other agencies, (c) grew in an open-water habitat (see Davies and Montagnoni (1985) for diagnostic criteria for open-water microatolls) and are not moated (see *Moating*; *Moats*); and finally (d) when sampling microatolls for dating, sample location should be systematically selected and replicated when inter-colony and site comparisons will be made. *Ad hoc* sampling across large microatolls several meters in diameter (e.g., randomly between perimeter and centre) may introduce age uncertainties exceeding 100 years.

### Oysters and encrusters

Encrusting organisms including oysters and barnacles occupy well-defined vertical zones on intertidal shores (Figure 4a) and have been used as sea-level indicators on tropical reef coasts, including those in the Southern China (Davis et al., 2000), Japan (Pirazzoli et al., 1985), Vietnam (Boyd, 2004), and the GBR (Beaman et al., 1994; Lewis

**Sea-level Indicators, Figure 4** (a) Modern oyster visor, exposed shoreline, Balding Bay, Great Barrier Reef (GBR), Australia; (b) Fossil oyster beds in sea cave at same location, used to infer 1.65 m higher sea level during mid-Holocene.

et al., 2008). Collectively these sessile intertidal organisms are commonly referred to as “fixed biological indicators” (FBIs). They are highly sensitive to long-term changes in water depth, and thus have great potential as sea-level indicators (Laborel, 1986; Pirazzoli, 1991).

The vertical range of FBIs is dependent on the tidal range and exposure to waves. On the central GBR, where the tide range is ~4 m, FBIs are confined with a 1.5 m interval that approximates the neap tide range (Lewis et al., 2008). Sea levels are determined by comparing the relative elevation of the upper and lower boundaries of fossil and extant species at the same locality. The precision of sea levels derived from these deposits may improve to within  $\pm 0.10$ – $0.25$  m if the relative relationships between different encrusters are carefully analyzed (Beaman et al., 1994; Baker and Haworth, 2000).

Davis et al. (2000) describe a mid-Holocene oyster bed at Big Wave Bay in Hong Kong at 1.7 m above a modern equivalent, but neither identifies the species nor reduce the height to a datum. *Ostrea* sp. oysters were used to establish sea-level history on the north coast of Vietnam, where fossil oysters in growth position were identified on near vertical limestone cliffs and in notches eroded into the cliff base. At this site, the fossil evidence is adjacent to modern oysters (Boyd, 2004). Modern *Ostrea* sp. oysters at the Vietnam study site extend from below low tide to around the mid-tide level. On the GBR, the oysters *Saccostrea cucullata* and *Crassostrea amasa* form conspicuous encrustations from MSL up to mean high water neaps (MHWN), although the upper and lower extent of *C. amasa*, and the precise elevation and range of *S. cucullata* encrustations vary widely within this range (Endean et al., 1956). *S. cucullata* forms distinctive visors 0.3–0.6 m thick between MHWN and MSL (Beaman et al., 1994), with the exact elevation varying with exposure. Lewis et al. (2008) suggested that *S. cucullata* could be restricted to vertical zone just 0.2–0.4 m wide (where tidal range is ~4 m), and argued these oysters allow robust reconstructions of paleo-sea level if the internal structure of a bed can be established and oyster age and elevations are accurately determined relative to modern oysters.

Barnacles and tube worm agglomerations have also been used as sea-level indicators on coral reefs (Pirazzoli et al., 1985; Baker et al., 2001; Lewis et al., 2008), although the later are more abundant on temperate coasts. Endean et al. (1956) detailed the vertical distributions of a range of intertidal organisms on Queensland's coastal islands, and considered that the barnacles *Octomeris brunnea* and *Tetraclitella* sp., which form crusts with high preservation potential, were particularly promising sea-level indicators. Pirazzoli et al. (1985) also concluded that *Octomeris* barnacles had great potential as very precise indicators of higher sea level stands in the Ryukyu Islands, but noted they are easily eroded after death if they remain in the intertidal. On the GBR, barnacles also tend to define higher sea levels. Lewis et al. (2008) suggested a barnacle 1.35 m above present sea level dated at 7,400 years BP was evidence for an earlier highstand on the central

GBR. A calibrated radiocarbon age of 5,310 years also exists for fossil barnacles located in a cave at Magnetic Island, offshore from Townsville (Beaman et al., 1994), but for the reasons discussed below, their sea-level significance remains ambiguous.

Unless buried or protected by rockfalls, encrustations are poorly preserved on open coasts as the rocks to which they attach are weathered and eroded (Scoffin, 1977). Fossil FBIs thus tend to be located at protected sites where the indicative meaning can be difficult to assess. For example, a fossil encrustation of *S. cucullata* in a protected cave at Balding Bay on Magnetic Island is ~1.65 m above the modern oyster bed. This fossil crust is presented as evidence of mid-Holocene sea levels 1.65 m above present persisting until around 4,000 years ago (Beaman et al., 1994), although it is arguable whether the fossil oyster's protected habitat is comparable to the modern oyster's exposed position (Figure 4b).

For most FBIs, interplay between growth and erosion means that long and continuous sea-level records are rare. Most encrustations are exposed to wave erosion, and if the rate of sea-level change is slow – or stable – the encrustation remains vulnerable to erosion. Rapid sea level falls that elevate the FBIs above the zone of wave attack offer the best prospects for FBI preservation. In the case of slowly rising sea levels, the entire encrustation assemblage may shift upwards, with a systematic vertical translation of species. Where change is fast, the encruster's response may not be sufficient to track it. Encrustations appear best to be able to document stillstands or slow sea-level changes, at which visors that extend tens of centimeters out from the rock surface may form. Over time this geometry increases vulnerability to breakage during storms, and intrinsically constrains the length and continuity of records preserved by these structures.

### Beachrock and cemented deposits

Beachrock is the lithified deposit formed when calcium carbonate cements consolidate beach sediments (see *Beach Rock*). Lithification occurs on relatively stable beaches beneath a cover of loose sediments that are later eroded to expose the beachrock outcrop (Figure 5). Beachrock can form in beaches composed of fine sands to boulders of terrigenous or biogenic provenance. Sedimentary structures such as bedding planes are preserved in many beachrocks. Some beachrocks are weakly cemented, with only the outer crust firmly indurated, but highly indurated massive beachrocks more than a meter thick also occur. The processes and conditions for beachrock formation and cementation have been well studied and debated (see Russell and MacIntyre, 1965; Stoddart and Cann, 1965; Hopley, 1986a); these details are not repeated here. Beaches on mainland shores, cays (see *Coral Cay Classification and Evolution*), and high islands may all host beachrock.

Beachrock durability and the consistency with which it forms within the intertidal have enticed researchers to use

it as a sea-level indicator. The exact upper limit of formation is, however, often poorly constrained, particularly where the tidal range and/or wave energy are high (Hopley, 1986a). The vertical dimensions of a beachrock outcrop vary with tidal range, with more compact beachrocks developing where tides are smaller. The upper limit is commonly around MHWS, but the precise upper limit to cementation is difficult to define as the degree of cementation often grades up the beach. This may partly reflect the rapidity with which cementation can occur (e.g., beachrocks on Magnetic Island developed in 6 months (Hopley, 1986a)). As cementation is so swift, it is possible that incipient beachrocks may form at infrequently achieved tidal levels if beaches are sufficiently stable.

Exposure to waves contributes further variability, with beachrocks on shores exposed to higher wave energy usually developing at higher elevations and being of greater vertical and horizontal extent. Kelletat (2006) argued that many beachrocks may be supratidal, but this is a minority view (Knight, 1997). On the northern GBR where the upper limits of modern beachrocks are between 1.6 and 2.9 m above tidal datum, MHWS is around 2.3 m (Davies and Montaggioni, 1985). Hopley (1986a) assessed the problems of reliably assigning an indicative meaning to beachrock elevation and concluded that the upper limit of beachrock formation should conservatively be considered to be as high as the highest astronomical tide (HAT). Uncertainties regarding whether the top of a paleo-beachrock reliably reflects a tidal level, swash effects, or is possibly an erosion surface demand that they be cautiously used as indicators of past sea level. The base of beachrock outcrops commonly lies near MLWS but this offers little utility for sea-level investigations as cementation may have occurred as the sea rose above this level at an earlier stage of lithification.

The efficacy of beachrocks as reliable sea-level indicators is further diminished by difficulties encountered in

establishing the age. Constituent bioclasts may be radiometrically dated to derive a maximum age, but this assumes that the bioclasts were incorporated soon after the contributing organism died (see *Radiocarbon ( $^{14}\text{C}$ ): Dating and Corals*). Calcium carbonate cement must be dated to determine a minimum age for the deposit, but this is technically difficult. Enough uncontaminated cement is difficult to harvest, and the possibility of multigenerational cementation and rejuvenation of the apparent age presents problems. Where beachrocks contain some quartz luminescence, dating – which establishes a depositional age – has been applied and produced promising preliminary results; paired luminescence and radiocarbon ages reveal the latter are systematically older by several hundred years, which may be attributed to the death to deposition lag (Thomas, 2009). Finally, although many beachrocks document former shoreline positions and have remained in situ, large beachrock slabs are dislodged by storms, and may be recemented intact but out of their original position. Only in situ beachrock should be used as a sea-level indicator.

Conglomerate platforms can be similar in appearance and elevation to coarse beachrock (see *Conglomerates*), but typically occur as subhorizontal platforms of poorly sorted cemented storm detritus (Montaggioni and Pirazzoli, 1984). Conglomerates around 1 m thick form platforms over windward reef flats on many Pacific reefs, and commonly form the foundations for reef islands (Figure 6). They are generally interpreted as storm deposits that accumulated near to sea level, an interpretation supported by the occurrence of in situ fossil microatolls over and sometimes within these deposits (Woodroffe et al., 1990). They are generally emergent features now perched above their contemporary equivalents – storm deposited gravel and boulder sheets (Pirazzoli and Montaggioni, 1986) – following sea level falls during the last few thousand years (Woodroffe, 2003).

Close petrographic examination of cements that bind conglomerates in French Polynesia identified two distinct sequences of marine cementation, the boundary between which marks the position of the marine water table. This boundary is generally close to mean low tide but locally varies with deposit permeability and reef flat drainage (Pirazzoli and Montaggioni, 1986). Below the boundary, cementation has occurred in both a marine phreatic and then a vadose environment, whereas above the boundary only vadose zone cements are present. Phreatic cementation overprinted by vadose cements suggests a sea level fall. Montaggioni and Pirazzoli (1984) conclude that conglomerates cannot be used to define the exact magnitude of a sea level fall, but are very useful indicators of sea-level change tendency in areas of low tidal range. The problems of dating beachrocks are all confronted with conglomerates, although as indicated above, in situ fossil microatolls buried beneath or growing over these deposits allow the ages of some conglomerates to be bracketed.

Other cemented outcrops including cay sandstones, dune eolianites, coffee rock, and silcrete that superficially

**Sea-level Indicators, Figure 5** Beachrock exposure at Heron Island, southern Great Barrier Reef (GBR).

resemble beachrock but have no consistent relationship to sea level also occur on reef coasts. Separate entries on phosphatic cay sandstone and eolianite should be consulted for details of description and formation (see *Phosphatic Cay Sandstone*; *Eolianite*). Both deposits are formed by supratidal lithification involving phosphatic or carbonate cements, and are hence useful directional sea-level indicators. For example, phosphatic cay sandstone forms when phosphatic cements derived from bird guano percolate sediments to the water table (Hopley, 1982), which on low islands and backshores can be close to sea level. Where relative sea levels change, this relationship may be altered – phosphate rock low in the tidal may indicate that sea levels have risen after deposit formation, but may also reflect changes in island shape and hydrology (see *Coral Cays – Geohydrology*).

### Mangrove deposits

Mangroves occur throughout the tropics in sheltered settings on shelf and mid-ocean coral reefs (see *Mangroves*). With only rare exceptions, mangroves grow in the

intertidal, mostly between MHWS and MLWS. Individual mangrove species have narrower vertical ranges that may yield even higher resolution sea-level signals if in situ stumps or roots are identified, but in complex habitats with increased diversity other factors may complicate these interpretations. For example, the vertical range of mangroves of the same species located less than 20 km apart varied by 0.5 m in North Queensland due to local differences in tidal behavior (Bunt et al., 1985). Such variability is problematic for precise sea-level reconstruction, especially where coastal and tidal configurations have changed through the Holocene. Larcombe et al. (1995) suggest an error of  $\pm 1.5$  m be applied on the GBR when measurements are not available, but on microtidal mid-ocean reefs this error may be reduced.

Mangrove deposits are either peats or muds. Mangrove peats are highly organic deposits dominated by mangrove-derived macrofossils (Figure 7). They are typical of microtidal environments with low terrigenous influx

**Sea-level Indicators, Figure 6** (a) Conglomerate platform with reef island above at Takuu, Papua New Guinea. (b) Exposure through conglomerate platform at Maiana, Kiribati.

**Sea-level Indicators, Figure 7** (a) Mangrove peat with in situ stumps preserved at shoreline of Madhiravadhoo, Maldives. (b) Close-up of peat in (a) showing gastropods associated with mangrove habitat.

(Woodroffe, 1988). Kelletat (1988, p. 227) stated that “the closest approximations to the mean sea level are provided by the base of the mangrove peat because these plants very precisely occupy the upper half of the tide range,” but he provided no data to support this claim. Mangrove peats have been used to infer late-Holocene sea-level changes on Caribbean and Pacific coral reefs, but the interpretations derived from them are controversial (Bloom, 1970; Woodroffe, 1988; Toscano and Macintyre, 2003; Blanchon, 2005). On the GBR, mangrove peats are restricted to offshore islands, or exposed shorelines where finer material is winnowed away. Mangrove *muds* are dominated by fine terrigenous silts and clays but contain mangrove pollen and sometimes remnants of mangroves and mangrove community associates such as oysters and other molluscan fragments (Grindrod and Rhodes, 1984). They are usually gray or grayish olive and buttery in texture. Mangrove muds mostly occur on reef coasts with large terrestrial catchments, where they overly beach and shallow sub-tidal sands and are interpreted as transgressive deposits (Grindrod and Rhodes, 1984).

Local variations in the indicative meaning of mangrove deposits, and of deposit taphonomy must be recognized when using them as sea-level indicators. Mangrove elevation may vary spatially as tidal curves differ geographically or through time, and can also be influenced by factors other than sea level, such as freshwater influx. Especially on exposed coasts, mangrove deposits are vulnerable to reworking during storms, and many mangrove deposits on shelf reefs were reworked during the postglacial transgression. Compaction and/or organic degradation can also lower a deposit, resulting in sea levels being underestimated. Postdepositional modifications are minimized where peats are thin and overlie less compactable strata such as bedrock or beach sands (Toscano and Macintyre, 2003), although Woodroffe (1988) suggested that greater root penetration from younger mangroves may increase compaction in thin peat deposits. Compaction of 10–20% is estimated for Holocene mangrove sequences overlying Pleistocene clays on the central GBR (Larcombe et al., 1995).

Well-preserved mangrove wood can be radiocarbon dated, and where it is in situ, its position on the plant can be identified (e.g., a buttress root), and it is proximal to modern counterparts, both relative elevation and age can be determined. Accurately and precisely dating mangrove muds is more difficult as the bulk samples necessary to harvest sufficient organics may integrate carbon with a wide range of true ages. Accelerator mass spectrometric (AMS) dating requires much smaller samples and can reduce the potential size of these errors, but cannot overcome issues of deposit reworking. The preservation of mangrove deposits (and materials) appears to have been improved during periods of rapid transgression, when increased depth rapidly isolated them from erosive shore processes and in some cases resulted in their burial (Hull, 2005). Woodroffe (1988) concluded that mangroves are good indicators of rapid transgression over millennia in

the stratigraphic record, but were poor sea-level indicators during periods of slow sea level rise, stillstand, or emergence due to issues of reworking and poor preservation.

### Marine notches

A marine notch is an indentation that may be centimeters to meters deep and of similar dimensions from base to top formed by erosion on coastal cliffs. They are prominent relative sea-level markers where uplift has exposed older reef limestones at the coast (Figure 8), and modern and fossil notches occur on the same cliff. Marine notches are formed during periods of relatively stable sea level, and hence multiple notches are required to establish a history of sea-level change. They are typically formed by a combination of corrosion and bioerosion (Dickinson, 2001), and achieve a morphology that reflects lithology, tidal traits, and wave exposure. The continuity of notch morphology through sites sheltered from vigorous wave action suggests that biological processes and solution are important in notch formation (Woodroffe, 2003). On coral reef coasts, marine notches are often asymmetric, with a gently inclined floor and prominent visors forming the roof (see *Notch and Visor*). Pirazzoli (1986, 1996) reviewed the various classifications and types of marine notches, and has linked key features of notch profile to tidal datums. He suggested that the base of modern marine notches was most often (in sheltered sites) close to the low tide level, with the retreat point coinciding with MSL, but others working in the Pacific contend that the retreat point is more often near the high tide level (Dickinson, 2001).

Different interpretations of the indicative meaning of notch features introduces uncertainty when they are to be

| Coral reefs        | Without reef flat features | Directional              | Poor (50 m to MLWS)                                                            | Good         | Good   | Good directional indicator, but indicative meaning ambiguous.                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
|                    | With reef flat features    | Finite                   | Good (–5 m to MLWS)                                                            | Good         | Good   | Depends on setting and features available.                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| Corals             | <i>Acropora palmata</i>    | Directional and finite   | Good (–5 m to MLWS)                                                            | Good         | High   | Caribbean only. In situ colonies indicates SL within 5 m. Rapid growth rate so thick frameworks also good directional indicator useful for transgressive sea levels – can be used with other features (coralline algae, other biofacies) to reconstruct transgressive history.                                                                                                                                                                                                                                |
|                    | Species assemblages        | Directional and finite   | Indicative meaning varies with assemblage<br>Precision variable – fair to good | Good         | High   | Biofacies with different compositions used to reconstruct depth changes related to sea-level change and framework growth. For example, at Mauritius, Montaggioni and Faure (1997) identified:<br>a <i>Pachyseris/Oulophylia</i> biofacies >20 m depth, an <i>Acropora</i> “tabulate” and Faviid community (20–6 m depth), a robust branching <i>Acropora</i> community (<6 m depth), and a <i>Pavona</i> community (<10 m). Different species and morphologies offer potential for improved depth resolution. |
|                    | Microatolls                | Finite                   | High. GBR open water (MLWS); moated (to MLWN). Mid-ocean (~MLW)                | High         | High   | Elevations vary with species. Massive <i>Porites</i> most commonly used. Excellent precision, reproducibility and preservation potential. Widely used in Indo-Pacific. Less common in Atlantic-Caribbean due to sea-level history.                                                                                                                                                                                                                                                                            |
| Sedimentary facies |                            | Directional, some finite | Indicative meaning varies with facies<br>Precision variable – poor to good     | Poor to fair | Poor   | Intertidal facies have greatest potential as both finite and directional indicators, but low preservation potential and as often detrital, low age resolution. Some may, however, become cemented and be better preserved.                                                                                                                                                                                                                                                                                    |
| Coralline algae    |                            | Finite                   | Most common in depths shallower than 2 m MLWS                                  | Good         | Good   | Very useful if preserved. Different species and morphologies offer potential for improved depth resolution.                                                                                                                                                                                                                                                                                                                                                                                                   |
| Molluscs           | Oysters                    | Finite                   | Intertidal                                                                     | Fair         | Good   | Different species have well-defined vertical ranges. Tend to be best preserved in protected settings difficult to compare directly with open water modern counterparts. Dating deposit age is difficult.                                                                                                                                                                                                                                                                                                      |
|                    | Barnacles                  | Finite                   | Intertidal                                                                     | Fair         | Good   | As for oysters.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |

Sea-level Indicators, Table 1 (Continued)

| Indicator         | Finite/<br>directional    | Elevation precision<br>(indicative<br>meaning)                                      | Preservation                         | Dating          | Comments                                                                                                                                                                                                                                                                                                 |
|-------------------|---------------------------|-------------------------------------------------------------------------------------|--------------------------------------|-----------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Beachrock         | Finite                    | To HAT, but may<br>be lower                                                         | Fair                                 | Low             | Intertidal formation though upper<br>limit can be difficult to define.<br>Dating very difficult. Can be<br>confused with supratidal<br>cemented deposits, although<br>cement type should resolve<br>identity.                                                                                            |
| Conglomerate      | Finite                    | MSL +1 m. Vadose/<br>phreatic cement<br>boundary<br>~MLW                            | Good                                 | Fair            | Interpreted as forming near to<br>MLW on storm-exposed flats.<br>Cemented initially in marine<br>phreatic environment, and then<br>partially in vadose zone as sea<br>level falls leave deposit<br>emergent. Cement boundaries<br>can improve indicative<br>meaning. Dating deposit age is<br>difficult. |
| Mangroves         | Finite and<br>directional | Intertidal, mostly<br>between MHWS<br>and MLWS                                      | Fair to poor                         | Poor to<br>good | Transgressive deposits best<br>preserved as isolated from<br>destructive processes that<br>degrade still stand deposits.<br>Deposits vulnerable to<br>compaction and erosion.<br>Integration of roots and<br>reworked older carbon can<br>make dating difficult.                                         |
| Microfossils      | Finite and<br>directional | Subtidal and<br>intertidal – varies<br>with species and<br>assemblages              | Can be good,<br>setting<br>dependent | Fair            | Reportedly can achieve<br>elevational precisions of $\pm 7$ cm<br>with statistical treatment of<br>data, but yields outcomes at<br>odds with other indicators.<br>Dating difficult due to small<br>size of materials and possibility<br>of reworking. New technique<br>on reefs with potential.          |
| Marine<br>notches | Finite                    | Intertidal. Retreat<br>point variably<br>argued to mark<br>MSL or high tide<br>mark | High                                 | Fair            | Varying interpretations of<br>morphology and relationship<br>with tidal datums. Dating relies<br>on encrusters, which can be<br>problematic.                                                                                                                                                             |

used as sea-level indicators but this is not a problem where sea-level changes are inferred from the differential elevations of modern and fossil features on the same cliff. The retreat points on modern and fossil notches tend to be well defined allowing relative elevations to be directly and relatively precisely measured. However, dating notches is more difficult, and usually involves dating encrusting shells (Nunn, et al., 2002; Boyd, 2004) and/or correlation with other dated features (Koba et al., 1982; Dickinson, 2001). Stalactites and flowstones may have formed on ancient notches since emergence, and may be dated to derive a minimum age of notch formation. Notches also occur on currently submerged reefs, and have similarly been used to establish former sea levels (Grigg et al., 2002).

### Microfossils

Microfossils such as pollen and foraminiferan tests have been used as sea-level indicators on the GBR, but are yet to be widely applied on other reefs. The approach exploits the tendency of many foraminiferans to occupy narrowly defined environmental niches that often stratify according to tidal levels (e.g., Gehrels, 1994). Where foraminiferans are well preserved in situ, they are useful indicators of sea level. Assemblages associated with broader tidal or environmental zones have been identified within the GBR (Haslett, 2001), but elevational precision is often poor.

The foraminiferan “transfer function” approach has been applied to develop precise sea-level records from foraminiferan data in temperate salt marshes and has recently been used on the GBR. A precision of  $\pm 0.07$  m

was reported for mesotidal mangrove coasts near Townsville (Horton et al., 2003) suggesting this technique has great promise for reconstructing sea-level histories on other sedimentary coastlines in reef settings where high-precision sea-level indicators such as microatolls and encrusting oysters are poorly represented. However, some difficulties with this methodology are evident where it hindcasts sea levels significantly above those documented by other indicators (Woodroffe, 2009). Foraminiferans are small and light; age is usually determined by AMS dating a bulk sample of foraminiferan tests picked from sediment under a microscope.

### Other indicators

A range of other geomorphic or sedimentological features with more limited application have also been associated with sea level on reefs. These include intertidal facies (Harvey et al., 2001); freshwater swamp, fluvial and other terrestrial facies or materials (Hopley, 1970); shore platforms, reef islands, boulder tracts and ramparts (Scoffin, 1977; Hopley, 1982; Davies and Montaggioni, 1985), and bioerosion and cementation signatures (Scoffin, 1977; Gischler and Lomando, 1997).

### Summary

The key attributes of the major sea-level indicators described above are summarized in Table 1.

Coral reefs are clearly rich repositories of sea-level information, with a great variety of sea-level indicators found in these environments. The quality of the sea-level data yielded by these indicators is variable in precision (elevational and age), and in the resolution with which sea level is actually and preserved. The most precise sea-level indicators record stillstand or small magnitude and/or slow sea-level changes, with only mangrove deposits and *Acropora palmata* frameworks documenting periods of rapid transgression. It is probable that improved technologies for detecting sea-level features and measuring their elevation – such as RTK GPS and swathe mapping – and also for harvesting material and establishing ages will improve the precision of data yielded from sea-level indicators from reefs into the future.

## SEDIMENT DURABILITY

Murray Ford

College of the Marshall Islands, Majuro, MH, Republic of Marshall Islands

### Definition

The ability of sediment constituents to resist destruction by physical forces.

### Introduction

The composition of calcareous reef sediment is a function of skeletal production by calcifying organisms; the destruction of skeletal remains by physical, biological, and chemical processes and sorting/mixing processes. The ability of detrital reef sediment to resist destruction by physical processes is a direct outcome of the durability of the sediment constituents. Highly durable constituents are less susceptible to physical destruction. Consequently, increasingly durable constituents are more likely to be present within sediment, which has endured significant transport and mixing. The degree to which the durability of constituent material is expressed in the composition of sediment is the function of the rate of sediment generation and the exposure to destructive processes. Highly durable, yet less productive, constituents can provide significant material to sedimentary systems, likewise highly productive, yet less durable, constituents can ultimately contribute little to a deposit, which will endure significant transport/mixing.

The physical destruction of reef-derived skeletal remains is driven by the entrainment and transport of material by hydrodynamic processes. Physical destruction and mechanical breakdown are terms used to group the processes of fragmentation and abrasion. Fragmentation is the physical fracturing of remains into discrete units (Lyman, 1994). In contrast, abrasion involves remains being physically ground down by collisions with other material resulting in a loss of mass and smoothing of the surface (Meldahl, 2001). The physical breakdown of reef framework and the skeletal remains of occupying organisms is widely considered to occur during high-energy events, that is, storm conditions (Scoffin, 1992; Grigg, 1995).

### Determining sediment durability

The durability of sediment and skeletal remains has been widely studied in both fields of sedimentology and paleontology. A range of techniques have been developed and applied to experimentally determine the physical durability of clasts. Primarily, these involve apparatus designed to replicate the destruction of material during transport. These studies can be broadly classified as sedimentological or paleontological studies, depending on the material used and the focus of the study.

Sedimentological studies have commonly focused on the physical abrasion of sediment as measured by change in clast weight. Change in clast weight has been used widely within fluvial systems to explain downstream fining of sediment in rivers, or along sediment transport pathways in coastal settings (see Lewin and Brewer, 2002 for methodological review). In contrast, paleontological studies tend to focus on the transformation of skeletal remains through physical, biological, and chemical processes, through the incorporation within the fossil record (Chave, 1960; Greenstein, 1991; Kotler et al., 1992; Beavington-Penney, 2004).

Nearly, all coral reef sediment comprises the skeletal remains of the reef framework builders and occupying organisms. This unique situation forces the examination of reef sediment to be an exercise in both sedimentology and paleontology. Reef sediments offer numerous challenges to the established methodologies developed with river-bed materials. First, in some of the earliest studies of this kind, Chave (1960) found that the durability of reef material varies more widely than the other types of sedimentary grains. In addition, reef sediments are composed of the skeletal remains of numerous organisms; each potentially displaying different levels of susceptibility to physical destruction, some seemingly delicate while others robust. The different degrees of durability and post-mortem life histories of reef sediment constituents complicate interpretations when compared to the relatively uniform sediment encountered in other coastal settings.

Chave (1960) conducted some of the earliest experiments assessing the durability of various constituents of carbonate sediment. Chave (1960) used a tumbling barrel to examine the abrasion of various reef species, including filamentous calcareous algae, Bryozoa, and various pelecypods, gastropods, corals, and echinoids. He found that the abrasion rates of experimental material varied considerably from total disintegration of Bryozoan clasts within an hour, through to *Nerita* (an intertidal snail), which after 183 h were worn but still recognizable to species level.

In a further study, Moberly (1968) isolated the most common individual components of sand from Hawaiian beaches and abraded them within tumbling barrels. These sediments contained a mix of volcanic material along with sediments of calcareous origin. The individual calcareous components analyzed were coral, *Halimeda*, molluscs, echinoids, foraminifera, and red algae. Moberly (1968) found that molluscs, foraminifera, echinoids, and red algae all display similar size related abrasion relationships. Larger clasts of these four components all produced more sediment after 50 h in the tumbling barrel than smaller clasts. Coral and *Halimeda* samples showed increased abrasion rates in smaller clast sizes. Moberly (1968) suggested that this is a function of the fibrous and spicular structure of the aragonitic corals and *Halimeda*. This is in contrast to Chave (1960), who found little correlation between mineralogy and durability. During tumbling barrel experiments, Hoskin et al. (1983) noted that dead coral yield almost twice as much sediment as living coral.

This was attributed to the abrasion of encrusting organisms and a skeletal structure weakened by bioerosion, suggesting a strong interplay between biological and physical destruction of reef sediment constituents.

Other experimental procedures have been developed and utilized to experimentally study the durability of skeletal remains while under transportation. While different from tumbling barrels, the techniques share a common theme in that a clast is exposed to an abrasive agent in an agitated state to simulate transport. Kotler et al. (1992) found through a series of abrasion experiments using orbital shakers that foraminiferal tests collected from modern reef assemblages at Discovery Bay, Jamaica were robust. However, differences in durability between species were discernible, with some more susceptible to abrasion than others, with some species that were completely destroyed during experimental runs.

### Implications of durability on sedimentary systems

Experimental investigations have found large variations in the relative durability of sediment constituents from various reef settings. While there is a lack of experimental consistency between approaches used to determine durability, there are broadly observed trends as to the ranking of constituent durability. Typically, coral and gastropods are the most durable, followed by foraminifera tests, echinoid spines, and calcareous algae. Physical durability has only been assessed for a limited range of sediment constituents and utility of results is hampered by inability to establish absolute measures of durability. However, there are several implications and uses of establishing the durability of key sediment constituents.

A detailed understanding the postmortem transportation history of sediment constituents can further aid in the selection of material for radiocarbon dating. Woodroffe et al. (2007) found AMS radiocarbon dates of coral grains to be a poor indicator of depositional age within a reef island deposit. This, Woodroffe et al. (2007) argue, is a function of the long period of time that the coral may be retained within the active sedimentary system prior to deposition. Tumbling barrel experiments tend to concur with this observation of higher coral durability, prompting caution when selecting material for radiocarbon dating. Having established that remains of calcareous algae *Halimeda* are rapidly destroyed postmortem, it can be assumed that the lag between time of death and time of deposition is brief, making *Halimeda* an ideal candidate for targeted AMS radiocarbon dating. Understanding of constituent durability is particularly useful in situations where understanding the lag between time of death and time of deposition underpins interpretations.

Similarly, inferences into the deposition of landforms can be strengthened through a thorough understanding of constituent durability. Material comprising carbonate landforms is often used to infer the transport and depositional history of such sediment (McLean and Stoddart, 1978; Yamano et al., 2000; Kench et al., 2005; Woodroffe

et al., 2007). The ability to infer the degree of transport endured by such a deposit can greatly improve such interpretations. For example, it could be argued that a landform comprised of less durable material has either been deposited rapidly or developed under low-energy settings. Reef islands that have been found to be comprised of a high percentage of *Halimeda* indicate a short lag time between sediment generation and island initiation. Kench et al. (2005) documented largely unmodified *Halimeda* facies within Maldivian Islands which they argue are concentrated within the “velu” or shallow lagoon facies. The inability of *Halimeda* to endure significant postmortem transport likely limits its utility in land building to low-energy settings.

### Conclusion

Within reef systems, biological and physical processes play key roles in the breakdown of sediment constituents and drive the formation of sedimentary deposits. The physical destruction of reef material is a significant feature of the sedimentary systems of coral reefs, the importance of which has largely been considered secondary to biological destruction. The susceptibility of sediment constituents to physical breakdown is a function of the durability of skeletal remains and the ability of environmental processes to initiate physical destruction. An understanding of skeletal durability provides unique insights into the postmortem history of constituents comprising a deposit, yielding increased powers to interpret attributes of a deposit.

### Definition

*Sediment dynamics.* The process of entrainment, transport, and deposition of detrital sediment within coral reef systems that controls the sediment budget status of a reef platform and development and change of sedimentary landforms within reef systems.

### Introduction

Coral reefs and reef sedimentary landforms are unique in that they are composed predominantly of calcium carbonate ( $\text{CaCO}_3$ ) that results almost entirely from ecological processes. The primary sources of reef carbonate are the skeletons of corals and other organisms or plants that induce  $\text{CaCO}_3$  deposition. Furthermore, their provenance is intrabasinal, with sediment production and deposition occurring either on, or in close proximity to, a reef platform. In addition to ecological processes, chemical precipitation can be locally important in the production of carbonate material (e.g., ooids), while terrestrial inputs can also impact locally on the sediment systems of fringing and barrier reefs.

Production of calcium carbonate by primary frame builders (corals and encrusting coralline algae) is an important component in reef development (Hubbard et al., 1990). Furthermore, carbonate production by primary frame builders and secondary benthic organisms interacts with a range of physical, chemical, and biological processes to “cycle” calcium carbonate within a reef system. Some of these processes aid in reef development; others control the generation of detrital sediment on reef

platforms, which is subsequently reincorporated and cemented into reef framework (Hubbard et al., 1990; Perry et al., 2008), stored on reef surfaces, transported off-reef (Hine et al., 1981; Hughes, 1999), transferred to infill lagoons (Macintyre et al., 1987; Kench, 1998a; Purdy and Gischler, 2005), or build sedimentary landforms such as coastal plains and reef islands (Maragos et al., 1973; Hopley, 1982; Calhoun and Fletcher, 1996; Woodroffe et al., 1999; Yamano et al., 2000, 2002).

As reef platforms constitute the net balance of calcium carbonate deposition in skeletons by primary producers and the redeposition of detrital materials in the reef framework the entire reef framework is considered a sedimentary unit. Typically sediment budget studies have attempted to quantify the net accumulation of carbonate material retained within reef systems (Hubbard et al., 1990; Perry et al., 2008) to establish the pattern of reef platform development at geological timescales. However, such studies have typically treated the generation of detrital material, which is not reincorporated into the reef framework, as losses to the reef system despite its importance in development of sedimentary landforms on or adjacent to reefs.

This entry adopts a view of sediment dynamics that is focused on the production, dispersal, and deposition of detrital carbonate at a range of timescales. The entry presents an overview of the processes that generate detrital sediment in coral reef systems, as these are the building blocks for sedimentary landform development. The mechanics and processes that activate sediment transport are examined, and difficulties in the use of standard sedimentological tools to infer sediment dynamics are discussed. Field studies that attempt to quantify sediment dispersal patterns and rates of transport are identified and discussed in light of the process controls on transport and their control on the development of sediment deposits. Insights into sediment dynamics are also examined based on observations of volumetric changes in sediment stores on reef systems from short to long timescales.

### Sediment generation

Sediment dynamics in coral systems are controlled by a number of processes that include hydrodynamic and biological processes that entrain, transport, and deposit sediments within reef systems. An overriding control is the rate of sediment supply to reef systems.

The supply of sediment in reef systems is principally governed by the production of calcium carbonate and its conversion to detrital material via a suite of physical, biological, and chemical processes.

### Calcium carbonate production

The production of calcium carbonate on reef platforms is modulated by the composition, distribution, and abundance of calcifying organisms on reefs. Producers form two broad groups. Primary producers are those organisms such as scleractinian corals and coralline algae whose skeletons

directly contribute to the framework of a reef platform. Secondary producers include a wide range of benthic organisms (foraminifera, molluscs, calcareous algae, echinoids, crustaceans) that dwell on the reef framework.

Production rates of a range of primary and secondary producers have been studied at the organism level (see Stearn et al., 1977; Hallock, 1981; Vecsei, 2001; Hart and Kench, 2007 for syntheses). Calcification rates for individual organisms range from 1.39 to 17.0 kg  $\text{CaCO}_3 \text{ m}^{-2} \text{ a}^{-1}$  for corals (Hughes, 1987; Eakin, 1992), 0.20–2.3 kg  $\text{CaCO}_3 \text{ m}^{-2} \text{ a}^{-1}$  for coralline algae (Stearn et al., 1977), 0.05–2.2 kg  $\text{CaCO}_3 \text{ m}^{-2} \text{ a}^{-1}$  for the calcareous algae *Halimeda* (Multer, 1988; Drew, 1983), 0.04–0.7 kg  $\text{CaCO}_3 \text{ m}^{-2} \text{ a}^{-1}$  for foraminifera (Sakai and Nishihiro, 1981; Tudhope and Scoffin, 1984), and 0.002–0.55 kg  $\text{CaCO}_3 \text{ m}^{-2} \text{ a}^{-1}$  for molluscs (Richard, 1981; Harney and Fletcher, 2003). A number of studies have also attempted to generate aggregated reef platform production estimates based on hydrochemical techniques (e.g., Smith and Kinsey, 1976; Smith and Harrison, 1977), census-based approaches using data on organism abundance and growth (Chave et al., 1972; Harney and Fletcher, 2003; Vecsei, 2004; Hart and Kench, 2007), geological estimates based on net accumulation of reefs (e.g., Ryan et al., 2001), and modeling techniques (Kleypas, 1997). Typical values from this aggregated approach range from 0.8 kg  $\text{CaCO}_3 \text{ m}^{-2} \text{ a}^{-1}$  for lagoonal environments, 1.6–5.0 kg  $\text{CaCO}_3 \text{ m}^{-2} \text{ a}^{-1}$  for reef flats, and greater than 2.0 kg  $\text{CaCO}_3 \text{ m}^{-2} \text{ a}^{-1}$  for forereef environments (Hart and Kench, 2007).

### Carbonate production vs. sediment generation

Estimates of carbonate production do not equate directly to the generation of detrital sediments within coral reefs. It is commonly assumed that sediment generation is a direct function of the growth rate of reef organisms and reefs, as biological factories yield a continuous supply of sediment (Scoffin et al., 1980; Kinsey, 1985; Hubbard et al., 1990). However, this assumption is overly simplistic, as the supply of sediment involves a complex sequence of processes, dependent not only on the growth rate of organisms, but their mechanical and biological breakdown and dispersal from reef source to sink.

Secondary producers contribute directly to a reef sediment reservoir upon death, and the rate of supply is controlled by the abundance, fecundity, life cycle, and turnover of organisms. However, primary producers only yield detrital sediment following breakdown by physical and biological processes.

Physical breakdown of coral is mainly associated with extreme hydrodynamic forces exerted by storm waves, tsunami, and cyclonic wave action that exceed the mechanical strength of coral colonies (Madin, 2005). Extreme waves have been reported to disturb and break corals to water depths up to 20 m (Scoffin, 1993). Total destruction of branching corals to water depths up to 12 m has also been reported (Stoddart, 1971; Woodley

et al., 1981; Van Woesik et al., 1991). Large reef blocks more than 4-m diameter further attest to the extreme forces able to mechanically break and transport material to the reef flat surface (Scoffin, 1993).

The susceptibility of coral to mechanical damage is related to the growth form of coral colonies. Arborescent, tabulate, and spindly branched growth morphologies are the most susceptible to damage, whereas massive forms tend to be more resistant to damage (Done, 1992; Massel and Done, 1993; Madin and Connolly, 2006).

The importance of high-energy events to the sediment reservoir is the potential for the rapid generation of large volumes of detrital material within reef systems. For example, cyclone Bebe that impacted Funafuti, Tuvalu, in 1972, stripped the living coral reef on the windward side of the atoll producing  $1.4 \times 10^6 \text{ m}^3$  of detrital material which was deposited on the reef flat surface (Maragos et al., 1973; Baines et al., 1974). The geomorphic implications of such temporal pulses in sediment generation are discussed later.

Bioerosion (biological substrate erosion) also plays a major role in the conversion of reef calcium carbonate production to detrital sediment and is facilitated by a wide range of reef-associated faunas, including species of fish and echinoids, and endolithic forms of sponges, bivalves, and worms (Spencer, 1992). These biological agents directly degrade primary and secondary reef frameworks, increasing susceptibility to physical and chemical erosion. Principal modes of bioerosion include (1) destruction of loose carbonate grains through mechanical or chemical disintegration during mastication and digestion of grains and the breakage of skeletons, (2) grazing of reef framework, and (3) destruction of framework through the action of macro and microboring organisms (Scoffin, 1987; Perry and Hepburn, 2008). Bioeroding processes can produce large amounts of sediment. For example, bioerosion by echinoids and fish may contribute 0.17–9.7 and 0.02–7.62 kg  $\text{CaCO}_3 \text{ m}^2 \text{ a}^{-1}$  to the sediment reservoir, respectively, and bioerosion by sponges 0.18–3.29 kg  $\text{CaCO}_3 \text{ m}^2 \text{ a}^{-1}$  (Scoffin et al., 1980; Hubbard et al., 1990; Bruggemann et al., 1996).

In summary, the relative role and temporal variations of physical and biological processes are clearly crucial to the supply of sediment for reef platform and sedimentary landform construction. There have been a number of attempts to develop sediment budgets for reef systems. However, the majority of these studies have been interested in net reef development rather than in the detailed quantification of the detrital sediment generated on reef platforms. Notable studies that have constructed detailed sediment budgets as part of studies of reef development include the following: Stearn and Scoffin (1977) who established a sediment generation rate of 17.5 kg  $\text{m}^2 \text{ a}^{-1}$  on Bellairs fringing Reef Barbados; Hubbard et al. (1990) who established a generation rate of 0.71 kg  $\text{m}^2 \text{ a}^{-1}$  at Cane Bay fringing reef, St Croix, US Virgin Islands; and Harney and Fletcher (2003) who identified a rate of sediment generation of 0.53 kg  $\text{m}^2 \text{ a}^{-1}$

from the fringing reef at Kailua Bay, Oahu. Eakin (1996) also estimated changes in sediment production on Uva Island, Panama as a consequence of the 1982–1983 El Niño event. He showed that sediment generation changed from an estimated  $6.09 \text{ kg m}^{-2} \text{ a}^{-1}$  prior to the El Niño event to  $6.92 \text{ kg m}^{-2} \text{ a}^{-1}$  after the event as a consequence of changes in bioerosion processes.

### Characteristics of reefal sediments

The reliance on ecological processes to generate sediments in coral reef environments imparts an unique signature on the texture (size) and hydrodynamic properties of reefal sediment. Maiklem (1968) defined two textural end members resulting from the dominance of biological or physical factors. The first is an “immature” sediment, which has an inherited grain-size distribution influenced by the abundance, availability, and type of organisms present, and their size properties. Second is a “mature” sediment whose grain-size distribution is the product of hydrodynamic modification of the inherited texture. It is important to note that in most reef settings there will be a range of textural types that reflect the differential role of biological and physical processes in deposit formation.

Biological influences on sediment texture are twofold. First, they control the physical properties of skeletal grains. The nature and type of calcium carbonate secretion govern grain density, size, shape, surface texture, and skeletal microarchitecture. These properties vary significantly between the different calcium carbonate secreting organisms. For example, the density of skeletal material ranges from  $1.0 \text{ g cm}^{-3}$  for composite deposits (Chave et al., 1972) to  $2.95 \text{ g cm}^{-3}$  for the octocoral *Heliopora* (Jell et al., 1965). Second, they influence the nature of grain breakdown before, during, and after deposition. In particular, the skeletal architecture and morphology of different producers govern the size distribution of breakdown products according to the Sorby principle (Sorby, 1879; Folk and Robles, 1964). Collectively, these variations in skeletal properties influence grain durability, which depending on the mechanical force applied to skeletons is a critical control on the breakdown of carbonate sediment. Chave (1960, 1962), recently updated by Ford (2009), found that grain durability varied by several orders of magnitude from the calcareous green algae *Halimeda*, which is rapidly abraded, to coral and molluscs, which are most durable and persistent in the reef sediment reservoir. Chave (1960) also found that durability of biogenic sediment was several times less than that of siliciclastic sediment.

Bioerosion processes are also an important agent in the alteration of physical properties of sediments. In particular, the differing modes of bioerosion influence the size range of sediments (Milliman, 1974; Hutchings, 1986; Scoffin, 1987). For example, grazing organisms can produce coarse particles, whereas microborers produce fine sand and silt-size particles.

### Hydrodynamic properties of carbonate sediments

Ultimately, reefal carbonate deposits represent a heterogeneous mix of skeletal organisms, each with varying size, shape, density, and durability. These properties impart distinctive hydrodynamic properties on reefal sediments, which along with fluid flow governs the initiation of sediment movement (Scoffin, 1987; Prager et al., 1996). In general, there have been few studies of the hydrodynamic characteristics of carbonate sediments.

Conventional analyses of sediment entrainment consider grain size as the principal indicator of the hydrodynamic behavior of grains. However, a number of studies have shown that due to the heterogeneous nature of reefal deposits, mean grain size of carbonate sediments is a poor predictor of hydrodynamic performance (Maiklem, 1968; Braithwaite, 1973; Kench and McLean, 1996). Maiklem (1968) and Braithwaite (1973) identified marked differences in settling behavior of individual skeletal particles of similar size (Figure 1a). For example, plate-shaped grains (e.g., *Marginopora* sp. or *Halimeda* sp.) settle at markedly slower rates than spherical grains of equivalent diameter (Figure 1). Such findings underscore the inadequacy of adopting size as an indicator of hydrodynamic behavior and can provide misleading interpretations of sediment dynamics in coral reef environments (Orme, 1977). For example, Kench and McLean (1997) compared the measured size and measured settling behavior of samples and found that size estimates (derived from the sieve method) caused overestimation of entrainment velocities, implying that deposits were only entrained under storm conditions. However, analysis of hydrodynamic performance revealed that samples were actually able to be mobilized under fair weather wave energy conditions, indicating that the sediment reservoir was considerably more dynamic than implied by size descriptors.

Consequently, Kench and McLean (1997) and Kench (1997) adopted “settling velocity” to describe a deposit’s hydrodynamic behavior and infer sedimentation processes. Kench and McLean (1996) also undertook threshold experiments on individual constituents and composite sediment deposits to generate a threshold of entrainment relationship (Figure 2). In contrast to the generation of threshold curves based on grain size (e.g., Prager et al., 1996), results identified the velocity of entrainment of skeletal deposits and grains of known settling velocity. Results showed significant variation in entrainment potential for individual skeletal constituents with plate-shaped grains, and gastropods among the most readily entrained clasts. Of note, threshold values for composite sediments were consistent with the field-derived estimates of Hine et al. (1981). More recently, Paphitis et al. (2002) developed empirical threshold relationships for shell fragments under unidirectional flow. In this approach, thresholds are based on the hydrodynamic size of grains. In addition, Yordanova and Hohenegger (2007) have examined the hydrodynamic settling and threshold properties of larger benthic foraminifera.

### Controls on sediment entrainment, transport, and deposition

The entrainment and dispersal of sediment on and adjacent to coral reefs is controlled by hydrodynamic processes and moderated by a number of biological processes. Instantaneous wave-induced currents are the primary mechanism for the entrainment of sediment in reef systems. In general, maximum wave-induced forces occur toward the edge of

reef platforms where wave breaking occurs, and these forces diminish across the reef as wave energy is dissipated (Roberts et al., 1992; Brander et al., 2004). Consequently, spatial and temporal gradients in the entrainment potential of sediments exist in reef systems. Such variations are predictable as tidal modulation of water level across reefs controls the temporal window within which gravity wave energy can propagate onto reef

flats. As water depth over reefs increases, a greater proportion of incident wave energy can leak onto reef flats, and in some instances, at highest tidal levels, waves propagate across the reef edge without breaking (Brander et al., 2004; Kench et al., 2009a). Water depth across reefs also controls the maximum height of reformed waves on a reef flat (Gourlay, 1994; Nelson, 1994; Hardy and Young, 1996) and, therefore, the boundary stresses available to entrain sediments. Hardy and Young (1996) found that the upper boundary of significant and maximum wave heights is limited to less than 40% and 60% of the reef flat water depth, respectively.

These temporal and spatial variations in wave energy have significance for modulating timeframes of sediment entrainment on coral reefs. Kench and Brander (2006a) introduced the *reef energy window index* to account for these variations. The index identifies the temporal window within which gravity wave energy can propagate onto reefs and stimulate sediment entrainment, a function of reef width, water depth over reefs, and incident wave conditions. In general, the index predicts that sediment transport is activated for longer periods on reefs that have small width and higher relative water depths (Kench and Brander, 2006a). Wide reefs and shallow water depths are characterized by short temporal windows within which the sediment transport system can be activated. For example, Brander et al. (2004) show that due to the elevated nature and broad width of the Warraber reef flat in Torres strait the sediment transport system is activated for only 1–2 h around high tide.

Once entrained, wave and tide-induced currents are able to transport sediment within reef systems. The rate of transport is governed by the current magnitude and settling velocity of particles. The direction of transport is largely controlled by the net and residual current flows within reef systems. The pathways and rates of sediment movement are of critical importance for the development of sedimentary landforms.

Biological agents are able to modify entrainment and depositional processes. Benthic organisms are able to preferentially entrain, disperse, and sort sediments (Scoffin, 1987). In particular, bioturbating organisms have been found to enhance transport by expelling sediment into the water column (Roberts et al., 1981; Frith, 1983) and thus are important in zones where hydrodynamic energy is insufficient to entrain sediment. de Vaugelas (1985a, b) and Tudhope and Scoffin (1984) show that bioturbation is also able to obliterate primary sediment textures through preferential sorting of finer grain sizes and the vertical mixing of sediment within the top 1.0 m of the sediment body.

In contrast, biological and chemical processes can play an active role in the deposition and stabilization of sediment and can have a strong influence on sediment texture. Seagrasses have the ability to baffle flow, inducing deposition of material, and bind sediment within root systems (Ginsburg and Lowenstam, 1958; Sellwood, 1986).

Neumann et al. (1970) found that the binding effect of seagrass and other flora significantly increased the threshold required to entrain sediment. In addition, a number of other mechanisms act to bind and stabilize sediments, which also raises the effective sediment thresholds. Such processes include physicochemical and organically induced precipitation of aragonite and Mg calcite crystals around grains to produce aggregates and cemented rocks, pelletization of sediment-ingesting organisms (e.g., Holothuria), and binding by algal mats (Scoffin, 1987).

### Sediment transport studies

A detailed understanding of sediment dynamics is important to better resolve depositional patterns in reef environments, predicting changes in sediment fluxes and reef-associated sedimentary landforms as a consequence of environmental change, and understanding the long-term evolution of geomorphic features on coral reefs. Furthermore, analysis of sediment transport pathways, rates of sediment transport, and process mechanisms driving transport are fundamental to support contemporary management of reef-associated sedimentary landforms and sediment resources, which are increasingly targeted as sources of aggregate by communities in coral reef settings (e.g., Brown and Dunne, 1988).

### Quantitative studies of contemporary sediment dynamics

There have been very few quantitative observations of sediment transport and the process mechanisms controlling transport processes in coral reef environments. In part, this is due to the practical difficulties of undertaking such measurements and the spatial and temporal variability in sediment transport in coral reef environments. Common approaches to establish sediment transport rates include sediment trapping, tracing tagged sediments, and more recently optical and acoustic sensor technologies.

Sediment transport pathways and rates of movement on fringing and forereef environments have been the focus of a number of studies, which have highlighted the off-reef flux of sediment. Hughes (1999) showed the downslope movement of larger clasts to talus slopes at Lizard Island, Great Barrier Reef. In the Caribbean, a number of studies have examined transport patterns, with many establishing off-reef transport that is responsible for development of large sand deposits (Meaney, 1973; Clack and Mountjoy, 1977; Hine et al., 1981; Land, 1979; Sadd, 1984; Hubbard, 1986; Hubbard et al., 1981). Using sediment tracers, Hubbard et al. (1990) showed that rates of sediment transport varied from average values of  $112 \text{ kg m}^{-1}$  under fair-weather conditions to  $745 \text{ kg m}^{-1}$  under storm conditions with an estimated total off-reef sediment transport of  $55,100 \text{ kg a}^{-1}$ .

A small number of studies have examined sediment transport patterns on reef flats around reef islands in the Great Barrier Reef (e.g., Flood, 1974; Hopley, 1981; Gourlay and Jell, 1993). Similarly, there have been few

attempts to quantify contemporary sediment transport rates in atoll systems. Guppy (1889) produced one of the earliest detrital sediment transport budgets from the Cocos (Keeling) atoll, Indian Ocean. Based on sediment trap data, Guppy estimated that  $1,500 \times 10^3 \text{ kg a}^{-1}$  of sediment was transported from ocean reef flats to shallow lagoon. Kench (1998a) and Kench and McLean (2004) reassessed this budget based on sediment fluxes through the shallow interisland channels on the atoll reef rim. Their data showed that significant differences in channel sediment transport occurred as a consequence of the reef width and hydrodynamic processes. On the high energy eastern side of the atoll, narrow reef widths and wave propagation onto the reef flat activated the transport system under fair-weather conditions and was efficient in transferring sediment through eastern channels at rates of  $268 \text{ kg day}^{-1}$ . The transport potential of these channels was limited by the supply of sediment. In contrast, broad reef flats (1.5 km) on the southern atoll acted to effectively dissipate wave energy. Consequently, the transport system was inactive under fair-weather conditions, with transport rates of  $\sim 2.2 \text{ kg day}^{-1}$ , and sediment accumulated in situ on reef flats. These channels were limited by the energy available to activate transport. However, under storm conditions higher wave energy propagated onto these reef flats and activated the transport system. Of note, measurements undertaken during a cyclone showed that sediment transport increased to 4,100 and 5,155  $\text{kg day}^{-1}$  through eastern and southern channels, respectively.

The majority of the above studies are site-specific case studies that have focused on bedload fluxes of sediment within coral reefs, which principally involves movement of sediments in the sand and gravel size range. These studies all show that transport is active under fair-weather conditions but can be substantially enhanced under higher energy (storm/cyclone) conditions.

A number of studies have also examined the fluxes and process mechanisms controlling suspended sediment fluxes in fringing, barrier, and platform reef systems (e.g., Davies and West, 1981; Orpin et al., 1999; Hoitink and Hoekstra, 2003). In particular, these studies have focused on the behavior of terrigenous inputs to reefs systems as they can pose severe ecological threats to reefs (e.g., Brodie and Furnas, 1996). Specific threats include reduction in photosynthetically active radiation (PAR), abrasion by sediment, reduction in hard substrate, and smothering by corals (Rogers, 1990; Fabricus and Wolanski, 2000; Dollar and Grigg, 2004). Recent investigations of suspended sediment fluxes have utilized high temporal resolution monitoring equipment that sample at the same rate as hydrodynamic measurements and allow long and continuous datasets to be obtained. Examples of such studies include Storlazzi et al. (2004) and Presto et al. (2006) on the fringing reef of southern Molokai, Hawaii; Orpin et al. (1999) in the Great Barrier Reef lagoon; and Hoitink and Hoekstra (2003) in Indonesia. Collectively, results from these investigations show that

fine sediments can be suspended under fair-weather conditions on reefs and in lagoons, net transport is a function of net current direction, fine sediments are effectively flushed from high-energy reef settings but aggregate in lower energy reef and lagoon environments, and that the orientation of the coast with respect to prevailing winds and waves is an important determinant on whether sediment is trapped or flushed from a reef system.

### Sedimentological interpretation of sediment dynamics

In lieu of detailed sediment transport measurements, interpretations of sediment transport and deposition in carbonate settings have been based on textural and skeletal component analysis (McKee et al., 1959; Folk and Robles, 1964; Flood et al., 1978; Wardlaw et al., 1992; Smithers et al., 1994; Randazzo and Baisley, 1995); broad (reef-wide) tide- and wave-driven current processes (Suhayda and Roberts, 1977; Flood and Scoffin, 1978; Hubbard et al., 1981; Lugo-Fernandez et al., 1994); and limestone classifications in which sediment size, skeletal constituents, and surrounding matrix are used to reflect the interaction of biological and hydrodynamic processes (Folk, 1962; Dunham, 1962; Tucker and Wright, 1990). Problems have been identified with these approaches, which have been attributed to the unique character of coral reef sediment systems and conventional tools used to characterize carbonate deposits (Orme, 1977; Scoffin, 1987).

Unlike siliciclastic environments, where production, transport, and depositional zones are commonly spatially and temporally separated, carbonate sediment is normally produced within the basin of deposition (Ham and Pray, 1962). There are a number of implications of this for interpretation of sediment deposits. First, zones of sediment production and deposition may be closely associated or overlap. Second, deposits may accumulate in situ with little influence from the hydrodynamic process regime. Therefore, the texture of such "death assemblages" has no relationship to the hydrodynamic regime. As a consequence the intrabasinal provenance of reefal sediment, together with the heterogeneous character of biogenic deposits, presents significant difficulty in the interpretation of sedimentation and sediment transport processes (Scoffin, 1992; Tucker and Wright, 1990).

An additional factor impeding the interpretation of sediment transport processes in reef environments results from the standard approach for analysis of carbonate sediment texture (Orme, 1977; Scoffin, 1987; Kench and McLean, 1996). Conventional grain-size distributions (derived from mechanical sieving) are unable to differentiate the relative importance of physical and biological processes in deposit formation (Orme, 1977; Kench, 1998b). Furthermore, as noted earlier, mechanically derived size distributions do not reflect the hydrodynamic characteristics of heterogeneous carbonate deposits.

Orme (1977) and Scoffin (1987) recognized these constraints and proposed that a “currents of removal” approach would provide a more powerful approach for interpreting deposit formation. A currents of removal approach was developed by Kench (1998b), which combined the hydrodynamic properties of sediments with measurements of wave energy to model the mobile portions of sediments. Such an approach enables the mobile and nonmobile fractions of deposits to be isolated and provides improved resolution of transport pathways in reef systems and the relative importance of transport and local sediment production processes in deposit formation.

The detection of sediment transport pathways in coral reefs has also been approached through the use of key skeletal constituents as sediment tracers. In this approach, organisms with known restricted production zones are used to reconstruct pathways of sediment movement based on both gradients in concentration of tracer constituents and the predictable taphonomic alteration of constituents in deposits. Examples include the use of the depth zonation of different species of *Halimeda* to infer off-reef transport at Grand Cayman Island, West Indies (Johns and Moore, 1981); foraminifera of known settling velocity to construct reef to lagoon transport pathways in the Cocos (Keeling) Islands, Indian Ocean (Kench, 1997) and the known taphonomic breakdown of the foraminifer *Baculogypsina* to construct transport patterns on Lizard Island fringing reef, Great Barrier Reef (Ford, 2009).

### Dynamics of sedimentary landforms

In general, studies of contemporary sediment transport processes in coral reefs have focused on short timescales (seconds to days), small spatial scales (point measurements), and examined pathways of transport. However, significant insights into sediment dynamics in reef systems can also be gained through examination of volumetric changes in sediment stores (e.g., reef islands, sand aprons) as expressed through morphological change. Typical morphological adjustments include shoreline erosion, accretion, sediment wash over, shoreline realignment, and island migration (Kench et al., 2009b). The major process controls on the formation and stability of reef sedimentary landforms are sediment supply and oceanographic regime. Wave action and its interaction with the coral reef surface determine current and sediment transport patterns that ultimately control the location of sediment deposition (Gourlay, 1988; Kench and Brander 2006a). Such processes are modulated by climate, and consequently, reef landforms exhibit rapid morphological adjustment to changes in these incident processes at a range of timescales.

At event scales, storms and hurricanes have both constructional and erosional impacts on reef sedimentary landforms (Figure 3). These contrasting responses reflect differences in storm frequency and texture of island-building materials (Bayliss-Smith, 1988). In settings with low storm frequency landforms are typically composed of sand-size sediments, which are susceptible to erosion

**Sediment Dynamics, Figure 3** Temporal variations in sediment storage and morphological change in reef islands: (a) Medium-term changes in sediment supply and (b) storm frequency and intensity leading to (c) a conceptual model of reef-associated landform response. Note: grey line in (c) depicts short-term shoreline morphodynamics. After Kench et al. (2009a, b).

during extreme events. Stoddart (1963) reported mass destruction of some reef top islands in Belize as a result of Hurricane Hattie, which depleted the island sediment reservoir. Kench et al. (2006, 2008) examined the morphological adjustments of Maldivian reef island sediment stores in response to the December 2004 Sumatran tsunami. They found that reef islands experienced erosion of shorelines by up to 9% of island area, overwash sedimentation which contributed up to 1,200 m<sup>3</sup> to island surfaces, lateral extension of beaches across reef flats, and evidence of off-reef transport down forereef sand chutes. Collectively, these observations indicated that the tsunami promoted exchange of sediment between the different sediment stores on the reef platform.

In contrast, in reef settings with high storm frequency islands are commonly composed of rubble on their exposed margins, while leeward and fringing reef-fronted coastal plains are composed of sand-size material. In such settings, large volumes of rubble can be generated in single events from coral communities on the outer reef. As noted earlier, Hurricane Bebe (1972) deposited  $1.4 \times 10^6$  m<sup>3</sup> of rubble as a rampart on the reef flat and islands of Funafuti Atoll, Tuvalu (Maragos et al., 1973).

Subsequent storms have reworked this rampart onto island shorelines, showing that the hurricane and subsequent storm processes added approximately 10% to island area (Baines and McLean, 1976). Sequential deposition of rubble ridges has also been identified in the late Holocene evolution of gravel islands in the Great Barrier Reef (Chivas et al., 1986; Hayne and Chappell, 2001).

At seasonal scales, Kench and Brander (2006b) examined the morphological sensitivity of 13 islands in the Maldives to predictable changes in wind and wave conditions controlled by the oscillating monsoons. Results identified rapid, seasonal morphological adjustments of island shorelines (up to 53 m of beach change) equating to 20,000 m<sup>3</sup> of sediment movement between seasons, despite morphological near-equilibrium on an annual basis. However, the magnitude of morphological change (sediment flux), and sensitivity of islands to change, were found to vary between islands as a function of reef platform shape, which controls wave refraction patterns.

At the decadal scale, shifts in prevailing wind fields and their influence on wave propagation (direction and energy) control erosion and accretion patterns on reef islands resulting in island migration (e.g., Verstappen, 1954; Flood, 1986). The Pacific decadal oscillation (PDO) and its effect on modulating storm frequency have been found to control multidecadal fluctuations in longshore sediment transport, resulting in erosion and accretion patterns of  $\pm 100$  m on the Kihei fringing reef shoreline, Maui (Rooney and Fletcher, 2005). Interannual El Niño Southern Oscillation (ENSO) variations have also been implicated in shoreline erosion and accretion patterns in Kiribati (Solomon and Forbes, 1999).

Variations in sediment supply either through changes in sediment generation on the reef flat or in net littoral transport gradients also exert a further control on landform change at medium to long timescales (e.g., Figure 3). However, while the role of process-driven changes on the sediment budget is somewhat predictable (Rooney and Fletcher, 2005; Kench et al., 2008), temporal variations in sediment generation of suitable grade for landform development and their influence on reef landform dynamics are poorly understood.

Differences and changes in accumulation history of reef sedimentary units at geological timescales may be explained through temporal variations in sediment supply and recognition that the relationship between reef carbonate productivity and sediment generation is nonlinear. For example, variations in sediment supply are likely to reflect shifts in the balance between reef growth and reef productivity for both primary and secondary sediment producers. During rapid catch-up growth mode, the reef structure was effective at retaining calcified products in the reef framework. However, as reefs reached wave base and vertical growth was constrained, excess carbonate was shed from the reef system and was either exported from the reef or made available for construction of sedimentary deposits. Consequently, the general trend for studies to identify the onset of development of sedimentary features (islands

and sand aprons) in the mid-Holocene (e.g., Woodroffe et al., 1999; Smithers et al., 1994; Harney et al., 2000; Woodroffe, 2003) may coincide with reefs either reaching sea level or reaching wave base and releasing a pulse of excess sediment for landform construction. In many reef settings, this may have coincided not only with a transition from vertical to lateral reef growth but also to reef flat emergence, which may have promoted shifts in reef flat ecology and thus carbonate production. As a consequence, the dominant constituents available for accumulation of sedimentary units may have shifted from sediments derived from frame builders (coral and coralline algae) to those derived from other sediment producers (e.g., foraminifera, calcareous green algae). Yamano et al. (2000) identified such ecological change, to a foraminifera-dominant reef platform following sea level stabilization at Green Island, as a key trigger for the onset of island formation and development. Similar reliance for island building on a narrow range of skeletal constituents has been identified by Woodroffe and Morrison (2001) in Makin Island, Kiribati.

The accumulation history of reef islands has also shown considerable variation in response to sediment supply. For example, on Warraber Island in the Torres Strait, island development has occurred incrementally over the past 3,000–5,000 years in response to continued supply of sediment (Woodroffe et al., 2007). At Hanalei Bay, Hawaii, Calhoun and Fletcher (1996) identified a gradual reduction in the rate of coastal progradation during the Holocene controlled by declining sediment supply. In contrast, Maldivian reef islands appear to have formed (primarily of *Halimeda*) in a 1,500-year window in the mid-Holocene and effectively ceased accumulation 3,500 years ago (Kench et al., 2005). Episodic land accumulation has also been identified in storm-dominated settings where reef development and island building have occurred in discrete depositional phases of storm-derived rubble (Maragos et al., 1973; Bayliss-Smith, 1988; Blanchon and Jones, 1997; Blanchon et al., 1997; Hubbard, 1997; Hayne and Chappell, 2001).

The reliance of some landforms on a select number of skeletal constituents also suggests that sediment availability through the late Holocene is also likely to have been influenced by biological perturbations (infestations of bioeroding organisms or mass death of secondary producers) that release pulses of sediment to the reef system and influence phases of deposition in sediment stores on reef systems. Consideration of the importance of sediment supply to reef sedimentary landforms highlights a number of issues fundamental to understanding morphological change and fluxes of sediment in storage zones within reef systems. It is commonly assumed that the reef “carbonate factory” produces a quasi-continual supply of sediment to build or maintain landforms. However, existing studies suggest that both the supply and composition of sediments available for land building can vary temporally in response to changes in reef growth/reef ecology (Yamano et al., 2000; Woodroffe, 2003), and these in turn influence

the accumulation behavior of reef sedimentary units. However, scientific understanding of the processes that “turn on” and “turn off” sediment supply as it relates to the construction of these sedimentary stores (islands, sand aprons) is poor. Exploratory modeling studies suggest that changes in sediment supply, either through alterations in sediment generation or littoral budgets, may be more important than sea level in affecting the stability of reef sedimentary landforms (Kench and Cowell, 2003; Woodroffe, 2003).

## Summary

The dynamics of carbonate sediment systems are controlled by the interaction of biological and physical processes that interact at a range of space and timescales to generate sediment, transfer sediment within reef systems, and form a suite of different sedimentary units within coral reefs. A large body of research exists on aspects of coral reef sedimentation including  $\text{CaCO}_3$  production, descriptions of carbonate sediment deposits and facies, and the geological development of coral reef platforms as sedimentary units. However, significant gaps exist in scientific understanding of the contemporary dynamics of carbonate sediments. Few studies have attempted to quantify the rate at which detrital sediment is produced in reef systems or the temporal variations in sediment generation. Furthermore, the physical process controls on the dispersal and deposition of carbonate sediments and the rates of sediment transport in modern coral reefs are also poorly resolved with field-based studies limited to only a few sites. Collectively, an improved understanding of contemporary sediment generation and transport processes is fundamental for understanding the controls on the development and morphological dynamics of sedimentary deposits in coral reefs.

## Definition

Together with the reef framework and carbonate cements, reef sediments contribute to the accretion of a coral reef. Scoffin (1992) reviewed the various contemporaneously occurring processes such as framework construction, reef

destruction (physical and biological), sediment transport and redeposition, and cementation, which eventually produce a reef limestone. Reef sediment composition and texture are also an expression of reef ecology, because the producers of reef sediments are largely reef-dwelling, carbonate-producing organisms.

### Composition

Carbonate-secreting organisms, the shells and skeletons of which eventually end up in reef sediments include Scleractinian corals, green (*Halimeda*, *Penicillus*) and red calcareous algae, mollusks, foraminifera, and echinoderms. Fragments of sponge, tunicate, or octocoral spicules, brachiopod shells, bryozoa, serpulids, and crustacean carapaces also occur but are volumetrically unimportant. Tests of pelagic organisms such as planktonic foraminifera and coccoliths may also be found occasionally in low quantities in reefal sediments. Usually, marginal reef sediment is dominated by fragments of coral

skeletons, red coralline algae, and *Halimeda* (Figure 1a and b). Mollusk shells and foraminifer test are less common. Lagoonal or platform interior sediments normally have high abundances of mollusk and foraminiferal shell fragments, with coral, coralline algae, and *Halimeda* occurring in lower abundances (Figure 1c). The classic study of Ginsburg (1956) in south Florida exemplifies these findings. A number of sediment distribution maps of major reef systems were compiled by Ginsburg and James (1974). Interestingly, all major barrier reef systems such as Australia, Belize, Florida, or New Caledonia are characterized by the terrestrial input and offshore intermixing of siliciclastic into carbonate sediments. The fine grain-size fraction ("mud") of lagoonal sediment is often composed of large parts of aragonite needles and nanograins originating from codiacean algae such as *Penicillus* (Stockman et al., 1967) (Figure 1d). *Halimeda* platelets appear to be especially abundant in restricted Caribbean reef lagoons (Gischler and Lomando, 1999),

**Sediments, Properties, Figure 1** Photograph of reefal sediments from Belize. (a) Marginal reef sand with fragments of *Halimeda*, coral, coralline algae, mollusks, forams (*Homotrema*), and echinoderms. (b) Thin-section micrograph of same sample. (c) Micrograph of lagoonal sediment with mollusk, foraminifer, and *Halimeda* fragments. (d) SEM-micrograph of carbonate mud from Belize atoll lagoon with codiacean aragonite needles and nanograins. (e) *Halimeda*-rich sediment from restricted Turneffe Islands lagoon. (f) Shallow lagoonal sediment with abundant nonskeletal grains (peloids).

(Figure 1e). In addition, nonskeletal grains such as ooids, peloids, and aggregate grains (grapestones, lumps) are found in a number of Caribbean and Indo-Pacific reef lagoons and carbonate platforms (Figure 1f). Peloids include ellipsoidal cemented fecal pellets, mud clasts, or micritized and rounded skeletal grains. Nonskeletal grains form in environments that are characterized by comparatively low sedimentation rates and where carbonate precipitation/cementation is favored (high temperature, elevated salinity, shallow and agitated water). According to Millman (1969), there is a fundamental difference between Atlantic and Indo-Pacific reef sediments in that nonskeletal grains are only abundant in the Caribbean. This author explained the difference, which he termed the “ooid problem,” by the lower depths of Caribbean as compared to Indo-Pacific reef lagoons. Exchange-rates of carbonate-rich waters that potentially lead to cementation and/or precipitation of nonskeletal grains are much higher in Caribbean lagoons (days) than in Indo-Pacific lagoons (weeks-months). However, the recent discovery of abundant non-skeletal grains in Indo-Pacific reefs (Braithwaite, 1994; Rankey and Reeder, 2009; Gischler, 2010) challenges this concept. More data on sediment occurrence and distribution are needed, especially from the >300 atolls in the Pacific Ocean. Characteristics of the various skeletal and nonskeletal grains are not discussed here. Detailed descriptions may be found in a number of standard textbooks (e.g., Millman, 1974; Tucker and Wright, 1990; Flügel, 2004).

### Texture

Unlike in siliciclastic sediments, grain-size analyses including the interpretation of means, medians, sorting, skewness, and kurtosis of reef sediments are only of limited environmental significance (Scoffin, 1992). First, the morphology and micro-architecture of carbonate grains determines the grain-size distributions of the breakdown products (“Sorby Principle”) (Figure 2). Second, the hydraulic characteristics of carbonate grains of the same size may be significantly different based on micro-architecture. For example, a bivalve mollusk shell fragment is much denser as compared to a coral fragment of the same size. Third, the way carbonate grains are broken down will also determine the resulting grain-size. Particle breakdown can be caused either by physical or biological agents. Biological breakdown in turn can occur in a number of ways, for example, by fish, by boring sponges and mollusks, or by bacteria. Fourth, the rate of carbonate production is decisive in that high-productivity environments are characterized by coarser grain-sizes as compared to places where the rate of carbonate production is low, particles are exposed to abrasion for a longer time period, and the resulting sediment is finer grained. Fifth, bioturbation, such as the intensive burrowing of callianassid shrimps in reef lagoons may fundamentally alter grain-size distribution in the upper meter of the sediment column. Sixth, trapping and binding in seagrass beds

or microbial mats in reef lagoons may lead to the accumulation of fine-grained sediment in areas where currents are comparably high. Because the traces of seagrass meadows and microbial mats are usually lost shortly after burial, fine grain-sizes may be found in high energy environments. Indeed, correlations between water depth and sediment grain-size in reefs is often statistically not significant. Still, there are rules of thumb in that, for example, marginal reef sediments contain lower volumes of fines than lagoonal sediments (e.g., Ginsburg, 1956). In order to be able to compare modern and ancient reef facies, some authors have used the Dunham (1962) nomenclature for reef sediment distribution maps even though the nomenclature was designed for rocks (e.g., Enos, 1974; Gischler and Lomando, 1999).

### The mud problem

In reef sediment studies, the composition of the grain-size fraction >125  $\mu\text{m}$  or >63  $\mu\text{m}$  is usually investigated using standard light microscopes. The composition of the grain-sized fraction <63  $\mu\text{m}$  (“mud”) is normally not included in quantitative analyses. The origin of mud has to be identified under SEM. Numerous studies in Atlantic, Indian, and Pacific Oceans have shown that lagoonal muds are largely of biogenic origin, that is, consist of very small skeletal grains and grain fragments (Stockman et al., 1967; Adjas et al., 1990; Gischler and Zingeler, 2002; Gischler, 2006). The ongoing controversy regarding the origin of carbonate mud largely concentrates on the Bahamas platforms. There, evidence for direct (codiacean aragonite needles) and indirect (bacteria) biological origin, inorganic aragonite precipitation, or combinations of both are considered (see, for example, discussion in Gischler and Zingeler, 2002).

In addition, the occurrence of whittings, suspensions of aragonite crystals and seawater are controversially discussed as expressions of spontaneous carbonate precipitation in the water column or resuspended sediment (e.g., Robbins et al., 1997; Broecker et al., 2000). An interesting new aspect was recently added to the discussion by Macintyre and Aronson (2006) who found evidence for high magnesium calcite precipitation in lagoonal waters of Belizian and Panamanian reefs.

### Sediment alteration

Physical breakdown of sediment grains predominates in marginal reef settings, whereas biologic breakdown including microboring is more important in lagoonal settings (Swinchatt, 1965; Perry, 2000). In general, sediment in marginal reef areas is exposed to taphonomic alteration for much shorter time periods as compared to lagoonal sediment, which is prone to slow consolidation, biological reworking (e.g., by callianassid crustaceans), recrystallization, and even dissolution (Perry, 1996). Reid and Macintyre (1998) show that numerous skeletal grain types in reefs and carbonate platforms are diagenetically altered in very early stages. For example, the aragonitic *Halimeda* plates start to recrystallize when the alga is

**Sediments, Properties, Figure 2** Grain-sizes produced by breakdown of carbonate grains in reefal sediments (from Scoffin, 1992).

still living. A further typical alteration of reef sediment is the development of micrite envelopes (Reid and Macintyre, 2000). They form due to the activity of microborers, which leave a network of small peripheral cavities that are subsequently filled by the precipitation of microcrystalline cement or fibrous aragonite. These grains are sometimes also referred to as cortoids. In case of complete micritization of grains, peloids may form (see above).

### Aspects of reef sediment dynamics

Gross production of calcium carbonate is highest in reef areas of high cover of corals and algae such as the marginal reef and fore reef environments. It is generally lowest in the back reef environments and intermediate in lagoonal coral patch reefs (Chave et al., 1972). Studies of sediment cycling in reefs have shown that the net production, that is, the amount of calcium carbonate retained in the reef as sediment and framework, may be

significantly lower than gross production as sediment tends to be exported to the fore reef and to deep water (Land, 1979; Hubbard et al., 1990). According to the excellent study of Hubbard et al. (1990), reefal carbonate production in a Caribbean reef system ranged from 0 to 5.78 kg  $\text{CaCO}_3/\text{m}^2/\text{year}$ , with a reef-wide average of 1.21 kg  $\text{CaCO}_3/\text{m}^2/\text{year}$ . Of this gross production, 0.91 kg  $\text{CaCO}_3/\text{m}^2/\text{year}$  remained in the reef whereas the missing 0.3 kg  $\text{CaCO}_3/\text{m}^2/\text{year}$  is lost from the reef. In some studies, radiometric ages (Maxwell, 1969; Gischler and Lomando, 2000) or combined  $^{14}\text{C}$  and  $^{210}\text{Pb}$  radioisotopes (Walbran, 1996) from reef sediments were used in order to decipher sediment dynamics and reworking, respectively. Li et al. (1997) successfully used grain-size distributions of foraminiferal tests in modern sediment samples in order to trace sediment redeposition within the fringing reefs of Grand Cayman.

## Summary

Reef sediments are largely composed of the shells and skeletons, as well as shell and skeleton fragments of carbonate-secreting organisms (skeletal grains). The most abundant include Scleractinian corals, Codiacean algae, red coralline algae, bivalve and gastropod mollusks, and benthic foraminifera. Nonskeletal grains such as ooids, peloids, and aggregates reach elevated abundances in some shallow lagoon and platform areas. Grain-sizes range from mud to rubble and boulders. Sand sizes are common on reef margins. Carbonate mud in reef lagoons is largely of biogenic origin; only the muds of the Bahamas appear to originate predominantly from physicochemical carbonate precipitation. Reef sediments are usually altered biologically and/or physically by breakage, boring, burrowing, encrustation, cementation, recrystallization, and dissolution. Carbonate production in reef amounts to several kg  $\text{CaCO}_3/\text{m}^2/\text{year}$  on average. Considerable amounts of carbonate sediments are exported from reefs and do not get incorporated in the framework.

## Definition

Seismic reef – reflected elastic wave image of the sedimentary architecture of a reef geomorphic body, and the expression of karst at significant subaerial surfaces within and/or at the top of the reef.

## Introduction to reflection seismology

Reflection seismology provides a large-scale, low-resolution view of geologic structures compared to the details of outcrop or modern sediment. Reflection seismology refers to the records of man-made elastic waves that travel in the subsurface and get reflected or refracted at rock body boundaries (Sheriff and Geldart, 1995). Rock properties governing the behavior of these waves are rock sonic velocity,  $V$ , and density,  $\rho$ . Sedimentary rocks are particularly well suited to seismic imaging, because, in general,  $V$  and  $\rho$  change gradually along bedding, but abruptly across bedding planes. Incident waves are split into a reflected part that travels upward, and a refracted part that continues downward in a different direction, and can be reflected at a deeper bed boundary. Multiple layers are imaged by the seismic tool, and the amplitude of the reflected waves is the reflection coefficient, RC. It is given by

$$\text{RC} = (\rho_2 V_2 - \rho_1 V_1) / (\rho_2 V_2 + \rho_1 V_1)$$

The products  $\rho V$  represent the acoustic impedance of the layers 1 (upper) and 2 (lower) respectively. Seismic surveys proceed by collecting data at closely spaced intervals

along surface profiles. The vertical seismic record is travel time, and must be converted to depth. This requires measuring velocity and density in boreholes, and correcting seismic velocities measured by the survey. In addition, horizontal reflectors will record reflections vertically below shot points, but dipping reflectors, abrupt terminations of reflectors, and reflections that originate out of the plane of the survey line (“side echoes”) must be corrected by “migration” of the reflections in the time domain (Figure 1). Correcting for dipping reflectors and abrupt reflector terminations is particularly important in imaging reefs, where fore-slopes can be steep (up to  $90^\circ$ ), and lateral facies changes can be abrupt (e.g., thin-to-thick bedded back reef sediments to massive bedded reef margin sediments).

Seismic resolution is of critical importance in imaging reefs. Generally, two reflectors can be recognized or resolved as separate events, if the distance between them is at least  $\frac{1}{4}$  wavelength. Wavelength,  $\lambda$ , is given by

$$\lambda = V/f$$

Where  $V$  is the sonic velocity and  $f$  is the frequency. Higher resolution results from a broad bandwidth of frequency. High-frequency waves are attenuated faster than low-frequency waves, and the frequency content will decrease with depth.

Seismic imaging is also affected by the type of survey that is collected. Two-dimensional (2D) seismic surveys are comprised of widely spaced profiles, generally greater than or equal to 1 km in spacing, and are more difficult to correct for dipping reflectors and side echoes, diminishing resolution. Three-dimensional (3D) seismic surveys have closely spaced shot and receiver positions (commonly  $\leq 25$ – $50$  m), and are more successfully migrated, increasing data quality and resolution. This has significantly improved the seismic imaging of seismic reefs (Masaffer et al., 2004).

## Rock properties, geophysical response, and the challenges of carbonate imaging

Carbonate rocks possess rock properties and geometries that present imaging challenges (Taner, 1997; Sarg and Schuelke, 2003).

1. For carbonate rocks  $V$  is large, often ranging from 4,500 to 6,000 m/s, and  $f$  is low because of high attenuation in massively bedded rocks with heterogeneous pore structures. These characteristics result in long wavelengths, and relatively low seismic resolution in reefs.
2. Velocity appears more controlled by the combined effects of depositional lithology, and diagenetic processes, like cementation and dissolution (Anselmetti and Eberli, 1997). The ranges within  $V_p$  and  $V_s$  are caused mainly by variations in amount of porosity and porosity type, and not by variations in mineralogy. Velocities show a positive correlation with density and an inverse correlation with porosity, but departures can

be significant. Rocks with moldic or intraframe porosity are dominated by matrix velocity and have higher velocities, whereas rocks with pervasive interparticle, intercrystalline, or microporosity have relatively lower velocities (Anselmetti and Eberli, 1997).

3. High-velocity carbonate layers also cause high-velocity heterogeneity and velocity anisotropy. As the incidence angle increases, the corresponding average travel velocity increases. Consequently, velocity increases with increasing offset of shot points to receiver points.
4. Carbonate platforms can have steeply dipping foreslopes that provide imaging challenges similar to those that occur with steeply dipping faults (e.g., dispersion and diffraction).

The complexity of bed and pore geometry within carbonate platform successions thus has a major effect on the geophysical response of carbonates (Sarg and Schuelke, 2003; Schlager, 2005). Platform margin reef facies are often massive bedded units with a complex amalgamation of mounded, and flat and dipping planar beds. This results in both horizontal and vertical anisotropy at the scale of one to tens or hundreds of meters. A mounded, chaotic seismic facies is common for reefs. Extensive karst formation can disrupt the normal bedding patterns making for chaotic stratal patterns, and dissolution expanded and enhanced fractures. This provides opportunity for complex ray paths, dispersion of wave fronts, and multiple diffraction points. Although often causing a distinctive chaotic seismic facies, with circular sinkhole and collapse features, resolution in this kind of terrain is generally lowered.

**Seismic Reflection, Figure 1** Seismic migration. Unmigrated reflections are plotted vertically below the shot point (b). This is correct for horizontal reflectors, but not for the dipping reflector shown in (a). Correction is done by migration, illustrated in (c) and (d). (c) shows all the possible sources that might have produced the reflection observed at shot point 1 (SP1), lying on a semicircle around SP1. (d) shows this process repeated for subsequent shot points, where the semicircles coincide in a zone on the right. This zone of coincident circles approximates the true position of the reflector (from Schlager, 2005).

## Reef architecture

The term reef denotes a wave-resistant buildup formed by the interplay of organic frame building, erosion, sedimentation, and cementation (Wright and Burchette, 1996). The basic controls on reef geometry are upward growth of the organic framework, current reinforcement by this structure, and sediment export by the reef factory. Reefs generally shed sediment of a wide range of sizes, and this material forms debris aprons that thin away from the reef core. Dunham (1970) distinguished between ecologic reefs, built and bound by organisms, and stratigraphic reefs where the binding may also be done by cementation of loose sediment. “Seismic reefs” defined by geometry and reflection character include either type. The seismic tool images reefs where many generations

**Seismic Reflection, Figure 2** 2D seismic. (a) Two-dimensional (2D) seismic image of the margin of western Bahama Bank. Modern margin with characteristic near-vertical wall, and cemented upper slope, overlapped by transparent facies of unconsolidated Holocene slope deposits. Steeply dipping diffractions help define the reef margin. Also present in lower right center of figure are a train of multiples generated from the hard interface between the Holocene sediments and the well-cemented Pleistocene slope deposits. Convergent fore-slope beds of Pleistocene periplatform and planktonic material occur seaward of the reef margin (modified after Eberli et al., 2004a). (b) Western Great Bahama Bank middle to lower slope showing discontinuous reflections on a channelized slope (within oval) (from Eberli et al., 2004a).

of reef growth were stacked to thicknesses of tens to hundreds of meters. Sand shoals that interfinger with reefs may also be included in the seismic reef unit.

### Reef seismic facies

Seismic reefs can be divided into a number of seismic facies (Figures 2, 3, and 4) (Sarg, 1988). The reef margin lithofacies is comprised of wave-resistant barrier reefs rimming the platform or belts of knoll and skeletal sands, and in many places, it has the most distinct seismic facies. Reef margins are heterogeneous, massively bedded

features, and image most commonly as mounded, chaotic seismic facies (Figures 2 and 3). Reef margins generally show abrupt lateral facies transitions to both platform interior, and fore-slope seismic facies. Platform interior lithofacies can range from near-reef sand aprons grading shelfward into restricted to normal marine lagoons. Depending on the degree of restriction, lagoons are composed of mixed muddy, sandy, and patch reef subfacies. The relative proportion of these subfacies is dependent on the grain size of local sediment production, and the efficiency of winnowing by waves and tidal currents.

**Seismic Reflection, Figure 3** NW Shelf Australia. Two-dimensional seismic of Tertiary carbonates off the northwest shelf of Australia, displaying a range of seismic facies across a broad passive margin shelf. Mounded, gently prograding, stacked buildups define the Miocene reef margin, and shelfward (to right) patch reefs or small isolated reef platforms occur within parallel bedded platform interior reflections. An older Paleocene-aged prograding bank displays oblique prograding geometry, where horizontal reflections define banktop bioclastic shoals, and dipping clinothems are composed of calcareous marls. The Pliocene section, overlying the mounded Miocene, is characterized by an eroded and truncated margin, and reflections dipping into the platform interior, and composed of bioclastic spillover sand lobes.

**Seismic Reflection, Figure 4** Seismic karst (a) Three-dimensional (3D) seismic reflection section of Jintan buildup (Miocene), Luconia Province, Malaysia. Interruptions of the reflections (arrows) are interpreted to represent a combination of fracturing and karst sinkholes. Most karst is associated with the top Zone Zb1, but some features reach to the top of the carbonate in the center of the Jintan buildup (from Vahrenkamp et al., 2004). (b) Horizon coherence or discontinuity time slice, 32 ms below the Zb1 unconformity. Discontinuities are made explicit by filtering the seismic to highlight discontinuities or areas where adjacent seismic events are different or discontinuous. In this time slice, sinkholes and other solution features are displayed as small circular to tubular features. The dark blotch (red arrow) is interpreted to represent a collapsed cave (from Vahrenkamp et al., 2004).

Seismically, the platform interior is characterized by parallel reflections of varying amplitude, where impedance contrasts are defined by porosity changes at bed boundaries (Figures 2 and 3). The seaward facing fore-slope lithofacies is a distinctly inclined unit, commonly displaying from 4° to 5° to near-vertical dips. Sediment is predominantly reworked platform material with pelagic admixtures, and has highly variable grain size from gentle muddy slopes to sandy or rubbly slopes with steep, planar foresets (Kenter, 1990). Seismically, the fore-slope is characterized by sigmoid to oblique clinoforms (Figures 2 and 3). Where channels dissect the slope, seismic facies are characterized by discontinuous reflectivity (Figure 2b). The toe-of-slope apron and basin lithofacies are moderately inclined ( $\geq 1.5^\circ$ ) to flat seafloors seaward of the fore-slope (Figure 3). Grain size is variable, ranging from well-defined graded beds, to fine-grained breccias, and muddy sediment, containing redeposited benthic and planktonic biota. Seismic facies are commonly convergent to parallel reflections of variable amplitude that may show downlapping terminations (Figures 2a and 3).

### Seismic expression of karst

Repeated exposure to fresh water results in solution and karst landscapes in humid carbonate terrains. These karst landscapes exhibit positive relief features like tower, or pinnacle karst that can be up to 300 m in relief, and negative dissolution features, such as sinkholes, caves, and karst collapse. The irregular shape and distribution of these features reflect seismic waves in a chaotic manner, which makes them hard to image in 2D seismic data. On 2D data, subaerial exposure and negative karst features often need to be inferred from their association with unconformities and erosional truncation, or the presence of chaotic seismic facies (Eberli et al., 2004b). Three-dimensional seismic data has largely overcome the problem of diffracted and dispersed seismic waves in karst terrains (Heubeck et al., 2004; Isern et al., 2004; Vahrenkamp et al., 2004). The concave-up sinkhole reflections of Figure 4 or irregular hummocky reflection patterns directly indicate negative karst features.

### Summary

Seismic imaging of carbonate platforms and coral reefs has markedly improved with the advent of modern 2D and 3D seismic data. Reflection seismic imaging does present challenges because of the unique characteristics of reefs, including high velocities, abrupt lateral facies changes, and steeply dipping fore-slope deposits. These result in lowered resolution, and diffractions and dispersion of elastic seismic waves that degrade the seismic images. Characteristic seismic facies include (1) mounded to chaotic seismic of reef margin and reef core lithofacies; (2) parallel, concordant reflectivity in back-reef and platform interior settings; (3) sigmoid to oblique prograding seismic facies in fore-slope environments, and (4) convergent to parallel reflection character in the toe-of-slope to

basin settings. Karst dissolution is expressed as concave upward and chaotic seismic facies in sinkhole and karst collapse terrains, and as positive relief, tower, and pinnacle features.

## SEISMIC REFRACTION

Nick Harvey  
 The University of Adelaide, SA, Australia

### Definition

*Seismic refraction.* Geophysical research method used to map the subsurface and internal structure of modern coral reefs.

### Introduction

Geophysical research methods such as seismic refraction and seismic reflection (see [Seismic Reflection](#)) techniques have been used to map the subsurface and internal structure of modern coral reefs. These methods rely upon the refraction or reflection of a seismic pulse (also referred to as a sonic, acoustic, or elastic pulse) at a seismic discontinuity, where there is a physical property contrast in the density and elasticity of the contiguous materials. In a geological context, the contrast may represent changes in mineralogy, lithology, porosity, cementation, diagenesis, or lithostatic pressure.

Seismic methods can thus be used to map subsurface discontinuities and determine thicknesses of strata allowing stratigraphic inferences to be made. Continuous seismic reflection (see [Seismic Reflection](#)) surveys can provide good inter-reefal data and in some cases, such as Purdy's study of the Belize reefs (Purdy, 1974), reveal the internal reef structure of modern reefs. However, the attenuation of the signal in continuous seismic reflection surveys is usually affected by steep reef surfaces so that sub-bottom reflectors become no longer detectable. In these cases, seismic refraction techniques are more useful.

In 1946, 1950, and 1952, seismic refraction programs were conducted on Pacific atolls, and data were obtained on the deep structure beneath Bikini, Kwajalein, and Eniwetak atolls (Dobrin and Perkins, 1954; Raitt, 1954, 1957). Near-surface seismic refraction investigations were also carried out in 1971 and 1972 at Eniwetak atoll, where at least two solution unconformities were identified (Henny et al., 1974) indicating the utility of the seismic refraction method for shallow subsurface investigations of reefs.

### Method

The seismic refraction method requires an increase in seismic velocity with depth across the refracting interface. The method involves the measurement of the time between the initiation of a seismic pulse at the shot point and its first arrival at the seismometer (detector), which is a measured distance from the shot point. These first arrivals (compressional refraction or p-waves) are usually the only ones considered in seismic refraction, although it is possible to use second arrivals (Dobrin, 1976). Arrival times for these waves are measured for incremental shot point/detector separations and plotted on a time distance graph as shown in [Figure 1a](#).

The seismic pulse for small studies using portable seismographs is usually generated at the shot point by either a hammer blow to a steel plate (to provide maximum coupling with the surface) or by the use of a small explosion. For a single-channel seismograph, the shot point is usually moved progressively away from the seismometer ([Figure 1b](#)), but with multichannel equipment, a larger shot is used in conjunction with a seismometer array.

The paths of the refracted waves, in a simple parallel two-layer case, travel in a straight line through a constant velocity medium  $V_1$  and are refracted along the boundary of the higher velocity layer  $V_2$  where there is a physical property contrast in the density and elasticity of the contiguous layers ([Figure 1b](#)). The angle of refraction ( $r$ ) is given by Snell's Law and is shown at point A on wavefront 7 in [Figure 1c](#) where the tangent to the sphere in the lower medium becomes perpendicular to the medium, and the ray travels along the boundary at the new speed  $V_2$  of the underlying strata. At a certain distance  $X_c$  ([Figure 1a](#)), the wave which has been refracted along the discontinuity will reach the surface at the same time as the one that has traveled the direct path in the lower velocity medium. At distances greater than this crossover time, the wave refracted along the surface of the discontinuity will reach the seismometer first and will therefore be represented on the seismic record as the first arrival. It is these first arrival or compressional refraction waves that are mostly used in refraction studies. There are different techniques for interpreting these seismic data.

### Reef studies using seismic refraction

Apart from the early use of deep seismic refraction in the 1940s and 1950s on the Pacific atolls, the use of shallow seismic refraction techniques for detailed modern reef studies is not apparent from the literature until the 1970s when such studies were conducted on Eniwetak atoll in the Pacific, using a 12-channel portable seismograph (Henny et al., 1974) and on the Great Barrier Reef of Australia using a single-channel portable seismograph (Harvey, 1977a, 1977b, 1986; Harvey et al., 1979; Harvey and Searle, 1983; Searle and Harvey, 1982; Searle et al., 1982). The use and adaptation of single-channel seismic refraction techniques, as a methodology for studying

**Seismic Refraction, Figure 1** (a) Arrival times for compressional refraction or p-waves are measured for incremental shot point/detector separations and plotted on a time–distance graph. (b) For a single-channel seismograph, the shot point is usually moved progressively away from the seismometer, but with multichannel equipment, a larger shot is used in conjunction with a seismometer array. The paths of the refracted waves, in a simple parallel two-layer case, travel in a straight line through a constant velocity medium  $V_1$  and are refracted along the boundary of the higher velocity layer  $V_2$  where there is a physical property contrast in the density and elasticity of the contiguous layers. (c) The angle of refraction ( $r$ ) is given by Snell's Law and is shown at point A on wavefront 7 where the tangent to the sphere in the lower medium becomes perpendicular to the boundary at the new speed  $V_2$  of the underlying strata.

reef-top structure is discussed by Harvey (1977a). The technique utilized across exposed reef surfaces employed a hammer and plate with an inertia trigger as a signal source and a geophone receiver. A major challenge was the insulation of electrical equipment in the marine

environment and also the adaptation of conventional steel plates to provide an elevated point of hammer contact when working in shallow reef pools. The technique was also used in shallow lagoon environments where transects were laid out using float lines and small dinghies. Although time consuming, it did allow seismic survey among closely spaced coral colonies where continuous recording hydrosondes could not be used. In this case, seismic detonators were used as a signal source and a hydrophone as a receiver (Harvey, 1977a).

These techniques were used to identify a refracting surface at three separate sites on the Great Barrier Reef where pre-Holocene sediments had previously been identified from borehole data. The seismic refractor at each of these sites was then correlated with a pre-Holocene substrate beneath the modern reef (Harvey et al., 1979).

Shallow seismic refraction studies were conducted on 30 individual reefs from Bewick Island ( $14^{\circ}26'S$ ) in the northern Great Barrier Reef to Lady Musgrave Reef ( $23^{\circ}24'S$ ) in the southern Great Barrier Reef with varying lengths of seismic profiling conducted for each reef (Harvey, 1977b, 1986). The combined seismic results from all 30 reefs show that the depth of the refractor varies from 3.9 to 24 m below the modern reef surface. This refractor on average is highest below the modern reef rim and lowest below the modern reef lagoons demonstrating that the relief on the older pre-Holocene substrate is correlated with the relief of the modern reef surface (Harvey 1986). At the start of the seismic refraction study program, there were only three reefs in the Great Barrier Reef where the pre-Holocene substrate had been identified in borehole data so that the refraction data were relied upon to identify the equivalent surface on the other 27 reefs. Subsequently, borehole data have been acquired for about half of these reefs and have verified the location of the pre-Holocene substrate (Harvey, 1986).

Searle and Harvey (1982) combine the use of inter-reefal continuous seismic profiling with reef-top shallow seismic refraction data across Michaelmas reef (Lat  $16^{\circ}35'S$ ) to demonstrate how the reef-top refracting surface is correlated with a strong seismic reflector on either side of the reef. This shallowest and most prominent sub-bottom reflector has been interpreted as the Holocene/pre-Holocene sedimentary boundary (see *Seismic Reflection*). However, this reflector is not detectable close to the reef-top surface because of attenuation of the reflection data. Thus, the refraction method is more useful in providing subsurface data on the reef-top itself and these data can be used together with the reflection data to provide a more complete record of the extent of the pre-Holocene substrate.

Searle et al. (1982) and Harvey and Searle (1983) discuss the interpretation of shallow seismic data for the Great Barrier Reef for both reefal and inter-reefal areas and demonstrate how seismic refraction and seismic reflection data can provide complementary data in order to obtain a better picture of the nature and extent of the pre-Holocene surface in the Great Barrier Reef region.

Seismic refraction data are also used in reef evolution studies to supplement geological data or to fill gaps in the data. For example, Johnson and Searle (1984) use refraction data in their identification of postglacial stratigraphy in the central Great Barrier Reef and Rees et al. (2006) use refraction data in their analysis of the Holocene granite-based reef systems in the northern Great Barrier Reef. These demonstrate the utility of the seismic refraction studies on reef-top surfaces, particularly where geological data do not exist.

## Summary

Seismic refraction is a geophysical research method that uses a refracted seismic pulse to map the subsurface and internal structure of modern coral reefs. Seismic refraction techniques are more useful than seismic reflection techniques in cases where the attenuation of the signal in continuous seismic reflection surveys is affected by steep reef surfaces so that sub-bottom reflectors become no longer detectable. However, Searle et al. (1982) and Harvey and Searle (1983) demonstrate how seismic refraction and seismic reflection techniques can provide complementary data in reef investigations.

## SHINGLE RIDGES

Jonathan Nott  
 James Cook University, Cairns, QLD, Australia

## Definition

Coral shingle ridges are convex up/top accumulations of coral fragments, often broken from near-shore reefs and deposited landward of the high tide level by storm waves. Over centuries to millennia, successive storms deposit a number of ridges that lie parallel or sub-parallel to the shore.

## Introduction

Coral shingle ridges often occur in locations where coral reefs occur close to shore. They are deposits of coral fragments forming a ridge that lies parallel or sub-parallel to the coast. These ridges can be up to 6 m high above the mean sea level, several tens of meters wide and can extend along the shore for hundreds of meters. Eye witness reports of their emplacement reveal that they are deposited during intense storms (often tropical cyclones) when coral fragments are eroded from near-shore reefs by wave action (Hughes, 1999; Davies, 1983; Baines et al., 1974; Rasser and Riegl, 2002; Nott, 2003). These ridges form a record of past tropical cyclones and/or intense storms and can be used to determine the frequency and magnitude of these events of many millennia. As such they can provide a valuable insight into the long-term behavior of storms over a region and help to elucidate the natural variability of the events from anthropogenic influences.

## Formation of coral shingle ridges

The source of the coral fragments deposited in the ridges can either come from living corals or it can also be transported from existing accumulations of coral shingle in the offshore zone. These offshore accumulations result from a number of erosional processes such as biodegradation and wave action during both storms and fair weather

conditions (Rasser and Riegl, 2002; Hughes, 1999). It is thought that the angle of the offshore reef slope plays a role in whether the eroded fragments are transported predominantly offshore or onshore. Steep reef fore-slopes, favor offshore transport of fragments, often to depths of greater than 50 m which is too deep to be reworked and transported by storm waves. Shallow sloping, and particularly wide reef fronts favor transport onshore and the formation of coral shingle ridges. However, some sites, such as Curacoa Island in the central Great Barrier Reef, Australia that are fronted by narrow, steep reef slopes have extensive coral shingle ridge development on land (Hayne and Chappell, 2001; Nott and Hayne, 2001). These sites with presumably minimal accumulation of coral shingle in the shallow waters of the reef and maximum accumulation of shingle in the deeper offshore waters below the wave base (depth to which waves will entrain and transport sediment on ocean floor), suggest that the onshore ridges could have formed from predominantly live coral fragments broken off during the storm. At other sites, however, there can be little doubt that onshore ridges were formed from the reworking of existing accumulations of shingle in the shallow waters offshore.

It is difficult to know whether the shingle ridge is deposited gradually during the storm, or as one, or a series of, sediment units moving landward from existing offshore accumulations. Scoffin (1993) has described coral shingle ridge building as ridges that

have been transported and deposited like large asymmetric waves of sediment; material picked up on the seaward side is rolled up the ridge and dropped down the advancing slope

suggesting, that an entire, or substantial part of an offshore accumulation of shingle is moved onshore as a single unit during the storm. If on the other hand, ridges accumulate gradually, then the ridge could be assumed to increase in height over a period of time during the storm. In this instance wave run-up (the uprush of waves against or over an object or sloping shoreline, respectively) may play a role in their formation.

It is likely that the height of an onshore coral shingle ridge is a function of the mean storm, still water level being the storm surge, tide and wave set-up (addition to the water level from broken waves) combined, and possibly wave run-up. Ascertaining to what extent wave run-up is responsible for the height of the resulting ridge is important, as run-up can equal or exceed the height of the storm surge depending upon various conditions. Wave run-up is a function of significant wave height ( $H_s$ ) and wave period/length, wave refraction/diffraction, bathymetry, beach slope angle, and roughness and permeability of beach material (Nielsen and Hanslow, 1991). With very rough, coarse-grained, permeable substrates Losada and Gimenez-Curto (1981) note wave run-up can be 0.30–0.75 times that of run-up on a sandy, largely impermeable beach under the same storm conditions. Observations of historical storm surge emplaced coral shingle ridges suggest that wave run-up may play an insignificant role. For

example, a 3.5-m-high ridge was deposited on Funafuti Atoll during Tropical Cyclone Bebe in 1971. The surge accompanying the storm was 5 m above the level of the reef flat, or mean low tide level, and 1.5 m higher than the elevation of the resulting ridge crest (Maragos et al., 1973). A similar situation occurred at Mission Beach, south of Cairns, North Queensland in Australia, where an intense tropical cyclone struck in March 1918. Here, a 4.5–5.1-m-high ridge of pumice was deposited by a surge as the tropical cyclone crossed the coast. Eyewitness observations and results from numerical storm surge and wave models of the event, along with knowledge of the tide level at the time, show that the storm tide (surge plus tide) and wave set-up combined, amounted to an inundation level of 4.7–4.9 m (Nott, 2003). This suggests that wave run-up could have only contributed 0.2–0.4 m of the ridge height at its highest elevation. Elsewhere, where the ridge is only 4.5 m high, the wave run-up does not appear to have contributed to the formation of the pumice ridge. It would appear therefore, that in at least some instances the height of the crest of coral shingle and pumice ridges is close to or less than the height of the storm tide and wave set-up combined. This does not mean, however, that progressive accumulation or accretion of a ridge cannot occur during the storm. But it does mean that wave run-up may not always be an important process in ridge accretion.

### Sedimentary and stratigraphic characteristics and preservation potential

Coral shingle ridges contain a number of distinct sedimentary facies or units of sediment. These include storm beach face, berm, crest and washover facies (Hayne and Chappell, 2001). Beach face and berm facies include porous, clast supported, coarse biogenic shingle deposits that occasionally dip seawards but are usually structureless. Crest facies are horizontally bedded and are finer-grained than beach face deposits. Washover facies are bedded, dip landward up to 15° and sometimes contain imbricated clasts (imbrication is a sedimentary feature where particles are arranged in an overlapping shingle-like pattern dipping in one direction). Each of these facies or units combines to make a storm deposit. Storm deposits are often separated by groundsurfaces being lenses of pumice pebbles and a weak sooty or earthy palaeosol (ancient soil). These groundsurfaces are really former groundsurfaces, or the surface of the feature that was exposed for a sufficient period of time between individual tropical cyclone events so that some soil development was able to take place. Ridges often contain only one storm deposit, but it is possible for two or more storm deposits to occur in one ridge. Careful excavation of the ridge is necessary in order to determine the number of storm deposits making up the ridge. Samples collected for geological dating from only one storm deposit, when more than one storm deposit is present, may bias the age determination of that ridge.

Coral shingle ridges often accumulate on the sheltered side of islands, presumably because on the exposed sides they are constantly removed by the largest or the most intense tropical cyclones affecting a region. The sheltered sides will experience diminished wave energy, but will still experience the full effects of the surge. As the wave energy is reduced, the likelihood of the ridge being removed during subsequent cyclones is lessened. Where, the preservation potential for ridges is high, such as on the lee side of islands, a number of ridges are sometimes able to accumulate over a period of time. Curacao Island on the Great Barrier Reef has 22 consecutive coral shingle ridges parallel to the shore on its northwestern or sheltered side. Individual ridges extend for over 100 m along the shore and rise to over 5 m above the mid-tide level (the tidal range here is approximately 3 m). The ridges were deposited by successive tropical cyclones so that new ridges are deposited seaward of the previously emplaced ridge. The age of the ridges increases progressively with distance, inland (Hayne and Chappell, 2001; Nott and Hayne, 2001). Curacao Island is typical of many sites that preserve coral shingle ridges; however, not all sites retain as many ridges. Elsewhere, only one or two ridges paralleling the shore are preserved. This is often due to the site exposure and the frequency of cyclones in the region. The time interval between cyclones will determine the extent to which compaction and lithification or induration of the ridge can proceed. Over a period of time, individual coral clasts within a ridge begin to weather or break down, and in so doing provide carbonate that will progressively cement clasts together. Cementation usually begins within the core of the ridge, and it is common for loose fragments to remain on the crest and sides of the ridge several centuries after deposition. The ridge becomes progressively resistant to further wave attack over time. However, looser fragments on the ridge crest can be removed and replaced by younger fragments if subsequent storm surges are sufficiently high to be able to overtop that ridge. In this fashion also, more recent storm deposits can be superimposed on older ones. Prior to stabilization, and depending upon the geomorphic setting, ridges can move inland by waves washing over the ridges and transporting clasts to the landward side of the ridge. The 19-km-long, 3.5-m-high and 35-m-wide coral shingle ridge deposited by Tropical Cyclone Bebe on Funafuti Atoll continued to move inland and along the shore for many years (Baines and McLean, 1976). Indeed, in some instances on coral atolls, the ridges will move across the reef flat and abut or lap onto existing ridges through normal, non-cyclonic, wave action. Individual storm or cyclone deposits and ridges will be more difficult to recognize at these locations compared to sites such as Curacao Island where individual ridges often remain separated from each other.

### Shingle ridges as records of the frequency and intensity of tropical cyclones

Coral shingle ridges can provide valuable data on the frequency and intensity of the tropical cyclones responsible

for their emplacement (Chappell et al., 1983; Chivas et al., 1986; Hayne and Chappell, 2001; Nott and Hayne, 2001; Nott, 2003). By dating most, if not all, of the ridges at a site, the total number of ridge building tropical cyclones over a period of time can be ascertained. Of course, the rate of ridge building is dependent upon the number of tropical cyclones passing the area with time and also the rate of coral reef replenishment or regeneration. Hayne and Chappell (2001) concluded that the narrow, fringing coral reef, which was the source of shingle for the ridges on Curacao Island, was able to regenerate after 80 years which was well below the apparent recurrence interval of ridge building (storm deposit) events of 280 years. The other ridge sites along the length of the Great Barrier Reef showed that ridge building events have occurred on an average every 177–280 years (Nott and Hayne, 2001). Furthermore all of these studies (Chappell et al., 1983; Chivas et al., 1986; Hayne and Chappell, 2001; Nott and Hayne, 2001; Nott, 2003) concluded that tropical cyclone frequencies have remained unchanged in the northeast Australian (Coral Sea) region over the last 3,000–5,000 years.

A method to determine the intensity of the prehistoric tropical cyclones responsible for building ridges was introduced by Nott and Hayne (2001) and Nott (2003). The height of these ridges was assumed to represent the minimum height of the storm inundation during the event responsible. The elevation of these features was accurately surveyed to datum, and samples of coral and/or shell radiocarbon dated to determine the minimum height and times of inundation, respectively. The height of this inundation was then related to the intensity of the palaeocyclone, which is determined through the use of numerical storm surge and shallow water wave models. The models are used to determine the relationship between surge height and central pressure for each shingle ridge location. In addition, the relationship between surge height and translational velocity of the cyclone, the radius of maximum winds and the track angle of the cyclone as it approaches and crosses the coast are determined. Model results are compared to the measured surge heights from recent or historical cyclone events near the study sites. The central pressure of the cyclone responsible for the formation of the ridge is then determined by modeling the magnitude of the surge plus wave set-up, wave run-up and tide required to inundate the ridge.

Nott and Hayne (2001) found that the coral shingle ridge sequences along the Great Barrier Reef were primarily recording only the largest or most intense tropical cyclones, and were not registering the smaller less intense events over a period of time. The ridge building events were very intense category 4 and category 5 tropical cyclones and they have had an average return interval of between 200 and 300 years over the past 5,000 years (Nott and Hayne, 2001).

The possible caveats to the technique for determining the magnitude of prehistoric tropical cyclones are the lack of inclusion of the influence of hydroisostasy on

the present day elevation of the prehistoric cyclone deposits, and the imprecision in calculating the wave run-up during the prehistoric event. Nott and Hayne (2001) and Nott (2003) recognize these possible caveats, and note that sea levels have fallen, due to hydroisostasy, over the period of the prehistoric record. However, if this is taken into account in the analysis of the intensity of the prehistoric storms, the older deposits (coral shingle ridges deposited between 3,000 and 5,500 years BP) should be higher in elevation than the younger more shoreward ridges. Topographic surveying of the ridges shows that this is often not the case. The coral shingle ridges compact over a period of time, and there is evidence also to suggest that the ridge crests have been overtopped by storm surge and waves, further reducing their height since deposition. Nott and Hayne (2001) suggested that this reduction in elevation of ridge crests would likely more than compensate for the effects of sea-level fall since termination of the Holocene transgression. In addition, if sea-level fall was taken into account it would suggest that the ridges deposited since approximately 2,500–3,000 years BP, or since sea levels stabilized close to their present height, would have been deposited by more intense cyclones. Such an interpretation would suggest that these storms were becoming more intense with time. Independent studies of other ridge sequences (sand and shell ridges) throughout the region and also studies using isotopic signatures of tropical cyclones in limestone stalagmites suggest that there has not been a substantial increase in the intensity of tropical cyclones in this region to the present day (Nott, 2006; Nott et al., 2007).

## Summary

Coral shingle ridges form where coral reefs lie close to shore. Waves during intense storms or tropical cyclones break fragile coral species into fragments that can accumulate as a (shingle) deposit landward of the high tide mark or as an offshore deposit that may or may not be transported landward at a later date. The onshore deposits of coral shingle are shaped into a ridge by the marine inundation constituting a storm surge, tide, wave set-up, wave action and wave run-up. Successive ridges are deposited with time so that multiple shore parallel ridges can eventually form into a ridge plain. Each new ridge is deposited seaward of the previous ridge and often, but not always, one ridge can be deposited during a single tropical cyclone event.

The ridge plains can provide a valuable record of the frequency and intensity of tropical cyclones for that region over several millennia. Recent examination of several ridge plains along the Great Barrier Reef region show that these ridges are often emplaced during intense tropical cyclones and these events occur on an average every two to three centuries. This is an order of magnitude greater than that suggested by the short historical record of these events in this region.

## SOILS OF LOW ELEVATION CORAL STRUCTURES

---

R. John Morrison

University of Wollongong, Wollongong, NSW, Australia

## Definition and introduction

Low elevation coral structures include atolls (essentially reefs of variable thickness built up by corals (and other organisms) resting on a volcanic base) and reef platforms having an elevation generally less than 5 m above mean sea level. They are unique to tropical and certain subtropical oceans since the reef-building organisms require water temperatures in excess of 22°C. These features are

widespread in the central and south Pacific, the central Indian Ocean, and parts of the Caribbean (Lesser Antilles and Bahamas), with a few examples in the Atlantic Ocean. Some countries consist entirely of low elevation coral structures, e.g., Kiribati, Maldives; others contain atoll groups, e.g., the outer Islands of the Seychelles; and some countries consist of mainly volcanic islands with a few isolated atolls, e.g., Ontong Java in the Solomon Islands.

Cumberland (1956) has identified six types of island (in the Pacific) partly or wholly associated with coral reefs, but in this chapter focus will be on more or less continuous emerged or slightly emerged calcareous reefs, with minimal comment on any non-calcareous structures present. The main structures will be low atolls (reefs surrounding a lagoon) where the maximum height of the emerged portion (usually less than 5 m) is made up of accumulations of broken reef material deposited by storms, or emerged coral platforms with no associated lagoon. Low-lying fringing reefs occur around many tropical islands, but these will not be considered here.

The widely varied nature of low elevation coral structures makes generalization difficult, but many have some features in common. They usually have limited land area and few natural resources. Such islands, particularly in the eastern Pacific, have limited supplies of fresh water and many are subject to prolonged droughts. The groundwater is often brackish (slightly salty). This peculiar environment has resulted in the development of a specialized flora – a plant community adapted to saline, alkaline soils, subject to water stress and salt spray. The natural vegetation is mostly strand species recruited from the Indo-Pacific or similar strand flora of the shores of islands of all kinds in the tropics. The agriculture is also rather specialized, often being restricted to coconuts, pandanus, breadfruit, and such root crops as *Colocasia* and *Cyrtosperma* grown in pits dug down to the groundwater table.

The properties of coral soils are, in general, dominated to a large extent by the calcareous nature of the parent material, whether or not this is mixed with volcanic materials. The soils tend to be shallow, alkaline, and coarse textured, having carbonatic mineralogy except where there have been relatively recent additions of volcanic material. The soils are generally of very low silica content. The fertility is highly dependent on the organic matter content. Organic matter can be high in undisturbed soils under natural vegetation, but can decrease dramatically as a result of inappropriate cultivation techniques, e.g., land clearance and weed control by fire.

As for all tropical soils, organic matter in coral soils performs an important role in the concentration and cycling of plant nutrients. In coral soils, however, a second role – that of moisture retention – is equally important. Since low coral structure soils are frequently sandy and excessively well drained, the moisture retention in the absence of organic matter is very low (see Morrison, 1990); the total amount of water retained often remains low, and plants are subject to water stress unless the rainfall is high and relatively constant or they can tap the freshwater lens.

## Soil forming factors on low elevation coral structures

Soil forming factors include climate, parent material, relief, hydrology, flora (and fauna), time, and humans, although these are not independent of each other. For low elevation coral structures, many of these factors are relatively constant, but some important distinguishing features occur. For example, the climate consists of two components – temperature and rainfall. The climate for the areas of interest is relatively constant with mean annual temperatures ranging from about 22 to 35°C, while the rainfall (as expressed in mean annual terms) can vary from about 700 to over 3,000 mm/yr. The impact of rainfall variations produces significant differences in the vegetation type and quantity, and this in turn leads to different amounts of organic matter being available for incorporation into soils. The result is that soils in similar geomorphological positions in “wet” and “dry” locations can be quite different (see Figure 1).

As noted above, the parent materials are dominated by calcareous solids derived from reef growth, with varying additions of ash, scoria, pumice, and guano. The materials are generally coarse-grained varying from accumulations of boulders and cobbles to materials dominated by sand with some silt material. Clay size materials are not abundant in these soils. Relief is not normally a key factor for low elevation coral soils, as the elevations are <10 m and slopes are usually very gentle.

Hydrology can be a significant factor, as the position of the groundwater table can influence soil properties, use, and management. In addition, the freshness of the groundwater may have an impact on the vegetation diversity and density and thus impact on organic matter availability for soil incorporation. As noted above, vegetation density and diversity are highly rainfall dependent, although the diversity is generally quite limited. The influence of fauna is limited with crabs digging burrows, pigs digging in soils, birds depositing guano, and some introduced species such as rats and goats damaging the vegetation. Time is also relatively constant for coral soils, as most low elevation structures have been formed in the last 5–7,000 years (Woodroffe, 2008). The influence of humans varies from place to place mainly by changing the vegetation from native species to coconut plantations or growing of other food crops.

## Diversity of low elevation coral soils

Given the limited variation in the soil-forming factors outlined above, it might be considered surprising that there are many variations in coral soils; this is not, however, the case. As an example, the soils of the islet of Abatao in Tarawa, Kiribati, will be described (Morrison and Seru, 1986). The survey work relating to this islet was done in the 1980s, while most of the islet was the Kiribati Government Agricultural Research Station and minimal human urban impact had occurred (see Figure 2).

On moving from the Ocean to the Lagoon, a number of different profiles were observed. Close to the ocean side,

**Soils of Low Elevation Coral Structures, Figure 1** Comparison of soils in stable mid-island positions in different rainfall locations (a) Tarawa (wet) and (b) Kiritimati (dry).

**Soils of Low Elevation Coral Structures, Figure 2** Cross-section of the central part of Abatao Islet, Tawara, Kiribati (modified from Morrison and Seru, 1986; soil profiles are described in the text).

Profile 12 showed minimal profile development. There was a thin surface horizon showing some organic matter accumulation, but little or no structure. This surficial layer overlay a thin, stony sand layer which, in turn, overlay coral rubble. Examination of the surrounding area indicated that the profile described represented the maximum

soil development in that part of the islet. Frequently patches of coarse light grey (10 YR 8/2 dry) sand up to 30 cm thick were observed with no evidence of soil development. On moving inland, an area of soils showing significantly different vegetation was observed (dominance of grasses). This Profile 11, consisted of a silty dark brown

surface layer (10–15 cm) overlying coarse sand to a depth of at least 1 m. The surface layer was dominated by grass roots. The lower portions of the profile (below 40 cm) were permanently saturated with groundwater that moves under the influence of the tides to within 10 cm of the soil surface), and on digging into the layer below 40 cm, there was a sulfurous odor.

Profile 10 lies further toward the lagoon, and has a well-developed A horizon varying from 15 to 20 cm in depth overlying a CA horizon with minimal organic content and soil structure to about 30–35 cm. There is again evidence of groundwater variation, but the maximum depth of movement up the profile is about 75 cm. Further to the lagoon side, Profile 9, lies in a mid-islet ridge position in slightly convex, undulating terrain. This profile, formed on sand that changes from medium to coarse with depth, has a clearly developed A horizon, 15–20 cm deep with weakly developed granular structure. This organic-rich (10% organic carbon) layer overlies structureless medium and coarse sand to a depth of more than 1 m, with no contact with the groundwater being observed.

Profile 8 lies on a second sand ridge up from the lagoon, and has a clearly developed A horizon with more than 10% organic carbon to a depth about 10 cm. This overlies a lower organic content layer (approximately 10–20 cm depth), and then there is a buried A horizon (approximately 20–30 cm depth) with significantly lower carbon content (1.6%), which in turn overlies at least 1 m of stony coarse sand. The buried A horizon resembles surface soils in more disturbed parts of Tarawa (Seru and Morrison, 1985). On the sand terrace closest to the lagoon lies Profile 7. This has a very weakly developed soil profile, showing a thin (<10 cm) A horizon, with a layer below this showing minimal organic matter incorporation to a depth of 30 cm, lying on top of coarse sand to a depth of more than 1 m. Groundwater influences were noted from about 80 cm down and the groundwater (slightly brackish) was contacted at about 90 cm.

Thus, on moving across an islet of about 650 m width, there is evidence of five different soils, with the properties being influenced by depth to rock, particle size of dominant materials, organic matter content, soil structure, and influence of groundwater. In terms of soil classification (Soil Survey Staff, 1975, 1999), all the soils would be Entisols (or Regosols or Lithosols), i.e., recent soils with minimal profile development, with separation at different hierarchical levels depending on the soil properties listed above.

Near the southern island of Abatao, a profile was observed that met the requirements for classification as a Mollisol (Soil Survey Staff, 1999) in that it had a deep (>50 cm), dark colored (Munsell color values 3 or less), high base status (base saturation >50%) surface layer having some structural features. This is most unusual, as Mollisols are typically the rich, productive soils of the Great Plains of North America. Their presence on Abatao further confirms the wide range of properties that can be found on low elevation coral structures.

Another area of Abatao also showed the presence of the Jemo series soil first identified by Fosberg (1954, 1957). These soils have laminated subsurface layers formed of carbonate materials cemented by phosphatic material believed to be derived from reaction between guano from birds nesting in the surrounding *Pisonia* trees and the underlying carbonate substratum. This genetic process has yet to be confirmed experimentally.

Such diverse combinations of soils have been observed on other low elevation coral structures in other islands of Kiribati (Jenkin and Foale, 1968; Woodroffe and Morrison, 2001; Morrison and Woodroffe, 2009), Tuvalu (Morrison 1990), Cook Islands (Bruce, 1972), Marshall Islands (Stone, 1951; Fosberg, 1956), Solomon Islands (Wall and Hansell, 1976), French Polynesia (Tercinier, 1956, 1969; Jamet, 1985), Hawaii (Foote et al, 1972), and Maldives and Aldabra (Spaull, 1979).

Soils derived from carbonate materials have a wide range of uses despite their limitations. Such materials are the only soils in several island groups (Tuvalu, Maldives) and are common soils in other groups (Cook Islands, several Caribbean Islands). Inhabitants of these islands have developed agricultural practices to produce a wide range of crops on such soils. These include coconuts, pandanus, breadfruit, citrus, and vegetables, with the specific practices and crops dependent on local factors, including the rainfall pattern. The use of mulches and pits dug down to the water table (e.g., see Figure 3) are among the practices utilized to achieve significant production (Small 1972; Chase 1992).

### Physicochemical and mineralogical properties of low elevation coral soils

#### Physicochemical properties and plant nutrition

Many of the properties of low coral structure soils are related to the organic matter content of the topsoil. Topsoil organic carbon values vary from about 1% to 20% depending on the age of the soil, the vegetation, climate, and soil management. In subsoils, organic carbon values

**Soils of Low Elevation Coral Structures, Figure 3** *Cyrtosperma* sp. ("Babai") planted in the water table in a pit dug into soils on Bonriki, Tarawa, Kiribati.

are always low (<0.5%) unless there has been considerable soil disturbance, e.g., due to the digging of *Cyrtosperma* pits. Nitrogen values usually follow the organic contents closely, and C:N ratios usually range from about 5–15 for topsoils to 8–20 for subsoils. Water retention against 1500 kPa (15 bar  $\approx$  wilting point) pressure is often closely correlated with organic matter content; values of 5–25% have been obtained for topsoils, while for subsoils the values are always low (1–4%). Cation exchange capacity is also closely related to organic matter for topsoils, with values in the range 6–60 cmol/kg, while the values for the sandy calcareous subsoils are usually less than 5 cmol/kg. Exchangeable magnesium values are generally around 3–8 cmol/kg, sodium contents are about 0.2 cmol/kg, unless there has been saltwater intrusion, but exchangeable potassium values are always low (<0.1 cmol/kg) unless there are substantial organic matter contents.

The calcium carbonate content is always high, ranging from 55% to 90% for topsoils and usually being greater than 90% for subsoils. This dominance of the environment by carbonate leads to high pH values; pH (water) values for topsoils are usually in the range 7.1–8.5 and for subsoils 7.5–9.0; pH (CaCl<sub>2</sub>, 0.01 mol/L) values usually range from 7.0 to 8.0 for topsoils and from 7.5 to 8.0 for subsoils. Extractable phosphorus (Olsen et al., 1954, procedure) values are generally low (5–15 mg/kg) for topsoils and very low (<1 mg/kg) for subsoils, but can be higher (>50 mg/kg) at sites with guano accumulation. The total phosphorus contents vary considerably, ranging from 500 to 50,000 mg/kg for topsoils and from 100 to 5000 mg/kg for subsoils. Total sulfur values are fairly constant at around 4000 mg/kg.

Thus it can be seen that in the low coral islands the soils are alkaline, with most of the soil “fertility” related to the accumulated organic material. Under these conditions, nitrification is favored but toxic accumulations of nitrate are unlikely unless there are unusual hydrological conditions. Volatilization of nitrogen as ammonia from ammonium and urea fertilizers will occur, with particularly large losses occurring if these materials are not incorporated. The availability of phosphorus is controlled by calcium activity; much fertilizer P will be precipitated as calcium phosphates or adsorbed on the surfaces of the carbonates. K availability is decreased by high Ca and/or Mg levels; the low levels of K in the coral limestone parent materials mean that this element will always be in short supply.

Supplies of available Ca and Mg are plentiful in low elevation coral soils but imbalances with K and micronutrients cause significant plant nutrition problems. Sulfur is usually available in small quantities from solution of limestone and from rainwater, but if crops with large S requirements are grown intensively, external additions will be required. Solubilities of Cu, Fe, Mn, and Zn decrease with increasing soil pH. Cu deficiencies are less related to soil pH than to the other micronutrients. Zn forms relatively insoluble zincates in calcareous soils and Fe uptake is reduced by high bicarbonate

concentrations in the soil solution. With the relatively low contents in coral limestone, all of these elements are likely to be highly deficient in low elevation coral soils (Deenik and Yost, 2006; Morrison, 1992).

### Mineralogy

As the soils of the low elevation coral structures are dominated by calcium carbonate, the dominant minerals are calcite and aragonite, which are the common forms of calcium carbonate deposited by reef-forming and reef-living organisms. Calcite contains varying amounts of magnesium (substituting for calcium in the mineral structure). If the magnesium content is >1%, the mineral is described as high magnesium calcite (HMC); other forms are referred to as low magnesium calcite (LMC). Variations in the relative aragonite/HMC/LMC contents depend on the origin of the carbonate material base for the soils. For example, Hammond (1969) found on Kiritimati (Kiribati) that aragonite was the dominant component, this mineral being present in the greatest amounts in the coarse fragments. Calcite was more abundant where foraminifera dominated the deposits. Most calcite was high in magnesium but LMC was present mainly in the coarse sand, very fine sand, and silt fractions. Aragonite, which forms the hard parts of corals or algae, and HMC from algal skeletal material, are more abundant in most shallow water marine environments than LMC, but among deep sea oozes rich in calcitic foraminifera and coccoliths, the more thermodynamically (under Earth-surface conditions) stable LMC is the predominant phase (Chave, 1962). In soils where guano deposits have been incorporated, apatite is usually found.

### Conclusions

Soils of low elevation coral structures around the globe display many similarities. The soils usually show minimal profile development, and are highly calcareous and heavily dependent on organic matter for moisture, nutrient retention and availability. Despite the limited variation in soil-forming factors, a range of soil profiles has been observed with organic matter content, particle size, depth to rock, and the influence of groundwater, leading to differences in profile features and potential utilization of the soils. The soils are usually classified as Entisols (Regosols or Lithosols), the major differences being in the soil moisture regime and the particle size class. Micronutrient and potassium deficiencies are encountered widely.

## SOLUTION PROCESSES/REEF EROSION

---

Stephen Trudgill

University of Cambridge, Cambridge, UK

## Definition

Calcium carbonate is soluble in water containing carbon dioxide, and thus, there has been focus on the chemical processes that take place in water, given the term “solution processes.” However, much erosion of calcium carbonate found in reef situations is actually effected by biological and mechanical processes, hence the wider term “reef erosion” is used to cover the range of processes involved.

## Solution processes

Much interest has been expressed in the question of whether or not limestones can be dissolved in seawater. The crux of the issue is that chemical analyses of surface seawater in open areas around reefs usually show that the waters are not frequently acid (with a pH often around 8.2) and are saturated with respect to calcium carbonate. If this is so, then it is difficult to envisage how calcium carbonate can move into solution in seawater from limestones (conversely, of course, it helps facilitate explanations of the formation of carbonate rocks by processes involving chemical precipitation). However, in intertidal situations, delicate, sculptured rock surface occur which, by analogy with freshwater situations, would appear to owe their origin to solution processes. An observer might conclude that these surface forms are produced by processes other than solution (for example, salt weathering or biological action), and the analogy with freshwater solution forms is both misleading and fortuitous. Alternatively, the conclusion can be that there are actually solution processes which facilitate the dissolution of limestones in

Solution Processes/Reef Erosion, Table 1 Erosion rates of reefs and reef limestones

seawater but which are not revealed by routine standard chemical analyses of open seawater. Geomorphological research has shown that both these possibilities can be true.

When inshore waters and intertidal rock pools are studied, this reveals that their chemistry can be substantially different to that of the open ocean. In particular, inshore waters in mangrove areas may actually become acidic if a peat substrate accumulates giving rise to significant solution erosion of limestone exposed in mangrove areas. More widely, in intertidal pools or other situations of closed or restricted water circulation, the existence of respiring organisms can substantially increase the amount of carbon dioxide in solution, and, therefore, the increasing potential for the dissolution of reef limestones. Emery (1946) showed that this will be especially the case at night when respiration output of carbon dioxide will not be balanced by photosynthetic uptake of carbon dioxide. Hence, solution of limestones is made possible in sea water due to biological respiration processes.

This may become more relevant in relation to future projections concerning atmospheric conditions and climate change. Recent work on the erosion of coral reefs

has focused on modeling the possible roles of climate change in reef erosion. This has discussed the effects of not only a rise in sea surface temperature (Sheppard, 2002; Carpenter et al., 2009) but also of acidification (Hoegh-Guldberg et al., 2007).

### Other erosion processes

While there has been considerable interest in the solution erosion of reefs and reef limestones, investigation has often revealed that some of the most powerful forces shaping the landforms involve biological erosion. However, this has sometimes been to the neglect of the processes common to all coasts, especially the physical processes. The wide range of processes which should be considered include wave action, wetting and drying, spray impact, abrasion by sand and pebbles, salt weathering and hydration, as well as solution and biological processes.

### Biological erosion

For the biological processes, both direct biological actions, such as grazing and boring by mollusks, and indirect actions, such as the alteration of carbonate chemical

equilibria, may be involved. Indeed, where dissolution processes appear to be important, this is usually in association with biological processes.

Many marine mollusks and other organisms graze algae, which are growing on or just within the rock surface. These grazers include mollusks such as Chitons, and gastropods with a rasping radula and fish. Other organisms bore into the reefs and reef limestones, including algae, sponges (especially *Cliona* and *Pione* species), bivalve mollusks (such as *Lithophaga*), barnacles (*Lithotrya*), and echinoderms (e.g., *Echinometra* species (Trudgill, 1985, pp. 137–155).

Bioerosion rates can be of the order of  $1\text{--}5\text{ kg m}^{-2}\text{ a}^{-1}$  (Table 1). Additionally, while Bak (1990) showed that bioerosion by sea urchins (echinoderms) in Pacific coral reef lagoons involved the direct destruction of  $12.5\text{ g m}^{-2}\text{ d}^{-1}$  ( $4.562\text{ kg m}^{-2}\text{ a}^{-1}$ ), Bak (1994) also showed that this can have an effect of weakening the reef structure. McClanahan (1995) calculated model values from published data of echinoid erosion of  $3.28\text{ g m}^{-2}\text{ d}^{-1}$  ( $1.197\text{ kg m}^{-2}\text{ a}^{-1}$ ) as compared to  $0.1699\text{ kg m}^{-2}\text{ a}^{-1}$  bioerosion by grazing fish.

## Zonation

Many of the processes of erosion of reef limestones are at their most powerful in the mid-intertidal: for example, wetting and drying cycles will decrease in number both upshore and downshore in relation to tidal cycles, upper shores being wetted and lower shores being exposed to drying only at extreme high spring tides. Other processes, for example abrasion, may be at a maximum in the lower shore, leading to planation at that level. However, for reefs themselves, where much of the erosion is biological, the focus of bioerosion is subtidal. In addition, sea levels have not been constant and the roles and erosion at higher and lower levels than at present have also to be taken into account in explaining present-day morphology.

## Exposure, process, and erosion rates

Whatever the erosion processes, exposure is a key factor. On the more exposed shores the relative importance of physical actions increases and this may be at the expense of biological processes. Trudgill (1976) showed that intertidal erosion rates of reef limestones on Aldabra Atoll, Indian Ocean, ranged from around  $1\text{ mm a}^{-1}$  on sheltered coasts where biological erosion dominated to  $4\text{--}5\text{ mm a}^{-1}$  on exposed coasts where physical wave action increased in significance. Similarly, Spencer (1985) showed that while reef limestones on Grand Cayman, West Indies eroded at a mean rate of  $0.99\text{ mm a}^{-1}$  the rates ranged from  $2.77\text{ mm a}^{-1}$  on sheltered coasts to  $2.77\text{ mm a}^{-1}$  were exposed. Further rates of erosion and their associated agencies are shown in Table 1.

## Summary

Earlier research focused on the relative importance of the differing erosion rates and clearly showed that biological

processes often dominate the erosion processes. This work was largely on growing reefs or reef limestones. The outlook is that more work will focus on the erosion of reefs following the deterioration of coral colonies in relation to increased anthropogenic sediment inputs and climate change.

## SOLUTION UNCONFORMITIES

Peter J. Davies  
 University of Sydney, Sydney, NSW, Australia

### Definition

Horizons within coral reef formations which have been exposed to the atmosphere during low sea level phases and display distinctive chemical weathering features.

The term *solution unconformity* was first coined by Schlanger (1963) as part of the landmark work on the drilling of Enewetak Atoll and referred to weathered unconformities produced within the atoll succession, at

approximately 33, 330, and 930 m. The unconformities exhibit characteristics that might develop on exposed limestone surfaces, and they are also rich in mangrove pollen. Similar characteristics occur in drill core from Bikini (Ladd et al., 1953, 1970; Ladd and Schlanger, 1960) and Midway (Lincoln and Schlanger, 1987). Later surveys discovered a series of solution unconformities caused by atoll-wide emergence events tied to variations in relative sea level (Quinn and Matthews, 1990; Wardlaw and Quinn, 1991). In the upper 371 m of the atoll, nine major unconformities have been recognized, six of which are within the Pliocene–Pleistocene. The unconformities are the result of atoll emergence (fall in sea level) with resultant development of chemical erosion as a result of meteoric dissolution of the limestones. Surface effects include soil and calcrete development and various degrees of surface karstification at small (karren) to large (solution rims, dolines conical, and tower features) scales. Below the surface, distinctive dissolution and precipitational fabrics and specific chemical signatures occur (James and Choquette, 1988). Upon re-submergence, this surface is preserved as a solution unconformity which can be identified by petrographic characteristics and a distinctive stable isotope signature. In drill core, criteria used for identifying solution unconformities include soil and caliche development, mineralogic and chemical changes (including isotopic changes), fabric changes, and color changes (development of red-brown color). Further, due to the fact that porosity development below and above the solution unconformity is different, unconformities exhibit velocity differences imaged on seismic data (Purdy, 1974; Davies, 1974; Harvey et al., 1979).

In the Great Barrier Reef, four unconformities have been identified at Heron Island (Davies, 1974), while six have been identified at Ribbon 5 (northern Great Barrier Reef) and representing low stands in the past 350,000 years (Webster and Davies, 2004). A special example of solution unconformity is that which occurs at the base of modern reefs and separating the reef from their foundations. Called the Thurber discontinuity (Thurber et al., 1965), it defines a hiatus between Holocene reefs dated by radiocarbon and underlying Pleistocene reef limestones dated by Uranium-series methods as Last Interglacial in age. This hiatus represents nearly 100,000 ka of exposure. In most reef systems, solution unconformities may represent exposure on more than one occasion.

## SPICULITE

David Hopley  
James Cook University, Townsville, Queensland,  
Australia

Spiculite is a relatively uncommon inclusion within the framework of coral reefs. It is formed from cemented spicules or sclerites found within the mass of either soft corals, especially Alcyonarians (Konishi, 1982; Alderslade and Fabricius, 2009) or sponges – the sclerosponges – usually at depths below active coral growth (Hartman, 1977; Hooper, 2009).

Most sponges contribute little to the sediments which become incorporated in reef rock. However, the massive aragonite skeletons of sclerosponges help to strengthen and build out the walls of caves and cryptic locations. The demosponges also secrete siliceous spicules with varying admixtures of fibrous materials, but the amount released to reef sediments is relatively small (Hartman, 1977). In contrast, the basal stalks of alcyonarians, especially the genus *Simularia*, which become consolidated through submarine cementation of densely concentrated coenenchymal spicules are attached firmly to the

substratum. Locally they form uniformly composed lenses, up to centimeters in thickness which may be encountered in cores from reef drilling (Konishi, 1982). Most sclerosponges have been reported to be aragonite, but some magnesium calcite species have also been found (Milliman, 1974).

## Definition

The simple, homogeneous structure of sponges (Phylum Porifera) distinguishes them from all other animals. They have no organ systems for reproduction, respiration, circulation, excretion, and digestion, and they are capable of extensive internal rearrangements in response to changed circumstances (e.g., Hartman and Reiswig, 1973; Bergquist, 1978, 1994). The resulting morphological versatility confers on sponges exceptional ability to recover from damage, propagate asexually, and develop symbiotic associations with a wide variety of plants, animals, and microbes. Sponges are also distinguished by astonishing biochemical diversity and novelty, with sponge metabolites accounting for nearly half of those reported from invertebrates (e.g., Harper et al., 2001). Sponges feed primarily on ultraplankton that they filter from water, as they pump it through a unique internal canal system, and many

species benefit from microbially mediated diet augmentation. Sexual reproduction involves release of sperm, or of both sperm and eggs, depending on the group; and the resulting larvae disperse relatively meager distances (Zea, 1993; Rützler, 2004; Maldonado, 2006).

### Sponges of coral reefs and linked ecosystems

On coral reefs, sponge biomass can exceed coral biomass, and sponges exhibit extreme diversity of growth forms (encrusting, massive, tubes, vases, bushes, runners, plates), sizes (a few mm to more than 2 m), and colors (every hue) (e.g., Diaz and Rützler, 2001; Wulff, 2001). Species diversity of sponges can be an order of magnitude greater than coral diversity. Van Soest (1994) compiled records of 640 species from the Caribbean, 259 from the Red Sea, 450 from the central Indian Ocean, 965 from Indonesia, and 717 from tropical Australia, and he directed attention to gaping holes in geographic distributional data. In a comprehensive biodiversity study of tropical Australian sponges, Hooper et al. (2002) corroborated the extreme geographic and habitat heterogeneity in sponge faunal composition reported in previous studies and estimated that fewer than 30% of sponge species are described. Taxonomic and quantification challenges pervade studies of all aspects of sponge ecology. Identification at least to genus is crucial because of the great variation among sponge species in functional roles. Abundance and individual size are best quantified by volume because many roles are played out in proportion to volume of living tissue (e.g., Wulff, 2001). Beneficial contributions of sponges to coral reefs and associated ecosystems include: efficient filtering of prokaryote plankton from the water column; binding living corals to the reef frame; facilitating reef regeneration; protecting mangrove prop roots and reef corals from invasion by boring organisms; providing food for charismatic animals such as hawksbill turtles, angelfishes, and nudibranchs; regenerating nutrients and adding to primary production through symbiotic microbes with special biochemical capabilities; harboring symbionts of virtually every animal phylum, as well as many algae, protists (including zooxanthellae), and prokaryotes; and attracting support for responsible human stewardship with aesthetically appealing colors and shapes (e.g., Rützler, 1978; Diaz and Rützler, 2001; Wulff, 2001).

### Filtering the water column

Sponges pump water through an internal canal system that is punctuated by chambers lined with flagellated cells, filtering out food and exhaling water that has been profoundly altered. By comparing incoming and outgoing water, and computing sponge energy budgets, Reiswig (1971, 1974, 1981) demonstrated extreme efficiency at removing particulate organic material of bacterial size range and discovered that sponges hosting large internal populations of bacteria ("bacteriosponges") could meet a significant portion of their metabolic needs by uptake of

dissolved organic material. Studies using recent technological advances to build on this foundation have determined that sponge feeding can be influenced by the following characteristics of the sponges and their environments: sponge internal morphology (body wall thickness, canal lengths and widths, density of choanocyte chambers), sponge size and shape (e.g., height above the substratum, ability to inhabit cryptic spaces), sediment in the water column (causing sponges to cease pumping or clog), symbionts (cyanobacteria and zooxanthellae that share food, bacteria that facilitate uptake of DOC, and macroscopic symbionts that can interfere with pumping), and concentration and types of plankton (e.g., heterotrophic bacteria, cyanobacteria, prochlorophytes, picoeukaryotes) in the environment (e.g., Reiswig, 1974; Pile, 1999; Yahel et al., 2003; Lesser, 2006; and a review in Rützler, 2004). Much remains to be learned of the overall balance of sponge influences on the water column, but it is clear that reduced water quality will result if sponges are diminished or lost from tropical and subtropical coastal habitats. Reiswig (1974) calculated that the sponges on the Jamaican fore-reef slope could fully filter the entire water column every 24 h, and by estimating the overall water column influence of sponges in Florida Bay, Peterson et al. (2006) concluded that a series of ecosystem-perturbing cyanobacteria blooms could be entirely explained by losses of sponges from many areas within the bay.

### Reef-building and rebuilding, carbonate balance, and coral survival

Sponges exert enormous influence on living corals and the reef framework, in an assortment of positive and negative roles that depend on sponge morphology, symbionts, and capacity to erode carbonate. Several species of coralline sponges add their solid aragonitic skeletons to caves, cryptic spaces within the frame, and deep reefs, where their independence from sunlight boosts their importance as carbonate accretors; but in general, sponge skeletons add little new solid material to recent reefs. Skeletons of non-coralline Demospongiae, the class to which most coral reef sponges belong, are typically composed of silica spicules and/or fibers of the protein spongin, and they disintegrate when not embedded in living tissue. A handful of sponge species in the orders Hadromerida and Haplosclerida rework solid carbonate into fine sediment (Hartman, 1977; Rützler, 2002). Silt-sized chips, created as they excavate burrows, infill cavities in the reef frame, where subsequent lithification cements permanently. On the negative side, the excavations weaken basal attachments of living corals, increasing their susceptibility to being disengaged from the reef frame and perishing in the surrounding sediments. Boring sponge abundance and activity may be promoted by elevated water column nutrient levels (e.g., Holmes, 1997), and details of the interaction boundary between the coral and sponge can substantially influence the excavations (e.g., Schönberg, 2003; López-Victoria et al., 2006).

Where coral skeletons are bared of living tissue, they are especially vulnerable to excavators. Goreau and Hartman (1966) pointed out that sponges growing over exposed carbonate can help protect against excavation, and that sponges can hold living corals in place even after their own skeletal attachments to the reef frame have been completely eroded (Hartman, 1977). Fore-reef patch reefs from which all sponges, except excavating and encrusting species, were removed suffered ten times the coral losses of control patches which retained their sponges (40% vs. 4% of corals lost) in only 6 months (review in Wulff, 2001).

Carbonate rubble can be regenerated into living reef if it is stabilized sufficiently for corals to colonize and survive. Sponges are able to quickly bind multiple pieces of rubble together, providing the stability required for carbonate-secreting organisms, such as encrusting coralline algae, to consolidate the rubble by growing between rubble pieces (Wulff, 2001). Carbonate sediments can also be bound by sponges (review in Rützler, 2004). Sponge-binding can make the difference between success and failure of reef regeneration in shallow zones, where rubble is otherwise continuously moved, and this process can prevent losses to gravity on deep talus slopes (Hartman, 1977). Under some circumstances, adding sponge fragments to rubble piles may be a low-cost, aesthetically appealing, and ecologically sustainable method of restoration for damaged reefs.

Demonstrated positive effects of sponges on corals mandate cautious interpretation of apparent overgrowth of corals, unless observations have been made in time series. Most confirmed coral overgrowths by sponges involve encrusting or excavating species, many of which are fueled in part by photosynthetic symbionts. Although only a few of the hundreds or thousands of sponge species in each of the regional coral reef faunas have been observed to overwhelm corals, local effects can be dramatic with respect to the areal extent of the infestation and the speed with which it occurs, and a variety of stresses, including temperature, sediment or other pollutants, and physical damage, may increase coral vulnerability to overgrowth (reviews in Rützler, 2002, 2004; Wulff, 2006c). Concern that loss of live corals to sponges may increase is bolstered by recent reports from Hawaii and the tropical eastern and western Pacific of invasions by nonnative species that can overgrow corals.

### Losses of sponges to disease, deteriorated water quality, and physical disturbance

Diseases of coral reef sponges appear to be increasing, but relevant data are rare. Because sponges disintegrate rapidly after death, particular individuals must be monitored over time in order to evaluate losses due to disease. Observations of disease prevalence require careful interpretation, as diseased sponges may recover. Most reports of significant losses due to disease have focused on large, conspicuous, or commercially valuable species, suggesting that many sponge losses are going unremarked

(Wulff, 2006a; Webster, 2007). Losses of up to 90% of the sponges at many seagrass sites in Florida Bay would never have been known if sponges had not been repeatedly monitored at those sites. In the sole study in which sponges have been repeatedly censused on a coral reef, half of the original 39 sponge species were lost in the course of only 14 years (Wulff, 2006a). Disease was implicated in at least some of these losses, but until additional sites are repeatedly censused, it is impossible to know how generally serious losses to disease and physiological collapse are.

Damage due to storms and other physical disturbances must be evaluated immediately after the disturbance, or with prior knowledge of the sponge communities, as damaged sponges can heal, and dead sponges vanish, within weeks. Amount of damage may not accurately indicate ultimate effects of disturbance for sponges. After a major hurricane in Jamaica, an inverse relationship between resistance to damage and recovery was revealed by monitoring sponges of 67 species for recovery or continued deterioration. A high proportion of massive sponges with tough skeletons resisted damage, but recovery was rarely successful for those that were damaged. By contrast, branching species suffered extensive damage, but recouped losses by reattaching as fragments (Wulff, 2006b).

High sponge species diversity, in combination with wide variation among sponge species in vulnerability to various abiotic stresses, renders sponges suitable for environmental quality monitoring in areas where sponge faunas have been studied well enough to interpret the patterns (e.g., Rützler, 2004; Alcolado, 2007).

### Spongivory

Relatively few animals are capable of consuming sponges, but predation has been demonstrated to constrain habitat or microhabitat distribution for some tropical species (review in Wulff, 2006c). Caribbean coral reef sponges are prevented from living in adjacent seagrass meadows by opportunistic feeding of seagrass-dwelling starfish, and mangrove species that are normally out of reach for reef-dwelling spongivores tend to be consumed when transplanted to coral reefs. Some sponge species inhabiting cryptic spaces within the reef frame, in the tropical western and eastern Pacific and in the Caribbean, are prevented from living on exposed surfaces by spongivores and normally herbivorous parrotfishes. By contrast, spongivores that routinely consume sponge species typical of their habitat do not appear to eliminate them, and some of the sponge species most frequently consumed remain the most abundant. Sponge specialists feed on sponge species with which they coexist in different ways. Nudibranchs may specialize on particular sponge species. Hawksbill turtles consume large quantities of only a handful of species in 3 of the 13 extant demosponge orders. Angelfishes instead feed in what has been termed smorgasbord fashion, with fish tending to consume small amounts of each of many sponge species (e.g., 70 species in gut contents; and direct observations of consumption of

23 species on a St. Croix reef and 64 species on a Panamanian reef). Palatability of a particular sponge species is predator specific, such that a species that is readily devoured by one predator, may be consumed in small portions by another, and completely rejected by others (review in Wulff, 2006c).

### Interactions with neighbors

Sponge overgrowth of sessile neighbors can be mediated by chemistry or growth rate and form, but time-series monitoring of apparent competitive interactions has often revealed that overgrowth is not progressing or that the net result is beneficial. Competitive interactions appear to be more likely to influence community composition in cryptic reef habitats and on mangrove prop roots. Sponges appear to be particularly good at tolerating, or even benefiting from, overgrowth by other sponges, and mutual benefit has been experimentally demonstrated for several cases of intimate heterospecific associations of tropical sponges (review in Wulff, 2006c).

### Symbiotic associations

The diversity, at all taxonomic levels, of symbionts hosted by sponges is extreme, but functional importance of intimate associations is not always understood. Sponges harbor a high diversity of bacteria, archaebacteria, and eukaryotic microorganisms (1694 16S rRNA sequences by the time of a review by Taylor et al., 2007), some of which have been shown to mediate carbon, nitrogen, or sulfur metabolism within sponges. The high proportion of phototrophic (i.e., obtaining at least half of their food from symbiotic cyanobacteria) sponges on the outer vs. inner Great Barrier Reef (GBR) and on the GBR vs. Caribbean reefs indicates how critical symbiont-mediated diet augmentation can be in oligotrophic water (Wilkinson and Cheshire, 1990).

Many hundreds of individual crustaceans, polychaetes, cnidarians, mollusks, fishes, echinoderms, and other animals have been discovered to be sheltering within a single sponge, and over a hundred species of inquilines have been found in representatives of a single sponge species. Sponges also grow over, or in tandem with, mangrove prop roots, a variety of colonial cnidarians, macroalgae, crustaceans, bivalves, and heterospecific sponges. Net results of symbioses range from mutualism to commensalism to parasitism and may be context dependent. Benefits traded by participants in mutualisms include protection against predators, substratum space, structural support, surface cleaning, inhibition of boring organisms, and nutritional collaboration (reviews by Rützler, 2004; Wulff, 2006c). Losses of sponges from tropical habitats would directly result in enormous additional biodiversity losses.

## SPURS AND GROOVES

Eugene A. Shinn  
University of South Florida, St. Petersburg, FL, USA

### Definition

Spurs and grooves form a comb-tooth structure common to many coral reef fronts. Best developed on the windward side of reefs, the structure consists of elongate channels or grooves, a few meters wide and deep, separated by seaward-extending coral ridges or spurs (Figure 1) (Maxwell, 1968, p. 110). Grooves are commonly floored with coral rubble or carbonate sand. Where actively accreting, spurs are covered with living corals. Where accretion has ceased, spurs harbor associated benthic organisms (Shinn, 1963).

### Morphology

One of the most obvious of reef features that is found worldwide is the spur-and-groove system, finger-like

coral projections located on the seaward side of coral reefs. Early authors called the spurs buttresses or simply the buttress zone (Odum and Odum, 1955). These features, clearly visible in aerial images, are restricted mainly to the windward side of reefs at or near the break in slopes. They serve as living breakwaters, reducing the height and force of waves impinging on the most exposed portion of the reef (Munk and Sargent, 1948). Actively forming spurs often begin growth at the tidally exposed reef flat and may extend outward to water depths of up to 20 m. Spur corals are also “tuned” to the direction and degree of wave energy. In especially high-energy, large-wave regimes such as Pacific atolls, spurs are narrow and closely spaced, i.e., more spurs and grooves per unit area (Cloud, 1959). In lower-energy areas, such as in the Caribbean and the Florida Keys, spurs tend to be wider, whereas the grooves separating them may or may not be wider (Goreau, 1959; Shinn, 1963). This is especially true for offshore barrier and bank reefs with reef flats that remain submerged most of the time. Spurs and intervening grooves tend to be narrower on fringing reefs backed by a rocky shore or sea cliff (Cloud, 1959; Shinn et al., 1981).

Spurs may reach 8 m in height. About 4 m is typical in the Atlantic. Grooves may be scoured to bedrock in the Caribbean but are generally lined with carbonate reef sand and coral debris (Newell, 1958; Goreau, 1959; Shinn, 1963).

### Composition

Work in Florida shows that rapidly growing, oriented colonies of *Acropora palmata* constructed most spurs there (Shinn, 1963; Shinn et al., 1981; Lidz et al., 2007; Lidz et al., 2008). Branches in oriented colonies face either seaward into oncoming waves or landward away from oncoming waves in parts of the Caribbean (Goreau, 1959). On Florida bank reefs, the branches are oriented mainly away from oncoming seas (Shinn, 1963). Branches of unoriented colonies that extend toward and into adjacent grooves are usually broken off during heavy weather and wave action. Branches oriented away from incoming seas are the most resistant to breakage during both normal and heavy seas, such as during hurricanes (Ball et al., 1967).

Constructional spurs are tuned to the waves much like bristlecone pines in the wind-blown tundra or other trees growing in the areas of prolonged high winds. Some erosion does occur and aids in the formation of the system, but the spurs are primarily constructional features.

### Processes

In the Pacific and other areas of high-intensity waves, the grooves can be mainly erosional in origin (Cloud, 1959, and observations by the author). Around Pacific atolls, grooves are usually scoured clean and may contain circular potholes enclosing rounded coral boulders (Cloud,

**Spurs and Grooves, Figure 1** Spurs and grooves at Sombrero Key Reef in the middle Florida Keys offer a popular dive site. The spurs are no longer growing but nonetheless consist of colorful hardbottom communities. (Reprinted from Lidz et al., 2007, with permission.)

1959). During rough sea conditions, the boulders grind the pothole sides, like a mortar and pestle, thus enlarging the pothole while reducing the diameter of the grinding boulder. Potholes are less common in the Caribbean, and grooves are often sand-filled.

In addition to being tuned to wave-energy level, spurs and grooves are also tuned to wave direction (Munk and Sargent, 1948). Spurs usually have a normal alignment to incoming waves even if the waves have been refracted, such as those occurring along the rims of the circular atolls. On the sides of the atolls, spurs are oblique to the reef trend. Spurs are generally absent on the leeward side of atolls or carbonate banks. Grooves are eroded into whatever substrate may exist, whether it is coral or other material produced by reef and reef-flat growth. In such cases, living coral and other encrusting organisms may populate the spurs. Thus, Pacific spurs are both erosional and constructional in origin (Guilcher, 1958). Spurs are further strengthened by growth of encrusting coralline red algae and internal marine precipitation of both aragonite and high-magnesium calcite. Precipitation is hastened by wave-generated pumping of seawater, which increases the volume of seawater flowing through the reef. Seawater is the source of precipitated carbonate minerals.

Where growth is especially rapid, corals may grow laterally to produce overhangs. Such overhangs can completely bridge grooves, forming tunnels that can reach tens of meters in length. The tunnels can develop over both constructional and erosional grooves. Cryptic algal and

coral species grow on the roofs of such tunnels. Frequency of major storm waves are likely to control the development of tunnels. Many tunnels formed in this way may simply terminate at a blind end, or they may have an upward-directed “escape” tunnel that serves as a relief valve. The valves may act as “blowholes” during stormy weather.

Throughout the Caribbean and Florida, corals show clear evidence of former sea-level changes. Paleoshorelines formed by still stands of sea level are especially visible as parallel bands of lime sand in aerial images. Early Holocene reefs that did not keep pace with rising sea level are common. These deeper coral reefs generally originated as fringing reefs but are now 20–30 m below sea level (Banks et al., 2007). The spurs and grooves fronting these deeper fossil reefs generally are narrower and more abundant than those on the shallow bank reefs.

### Summary

Spur-and-groove structures always form on the windward side of coral reefs in response to unidirectional wave energy. Where wave energy is consistently high, as on the Pacific atolls, grooves are mostly erosional in origin. In areas of lesser wave energy such as in Florida and the Caribbean, the grooves are constructional with spurs growing on either side of sand- or rubble-filled channels. Florida and Caribbean spurs consist mainly of oriented branches of *Acropora palmata*. The most common, and wave resistant, orientation of *A. palmata* branches is

landward. A tunnel forms where corals are able to grow over grooves. If both ends of the tunnel remain open, the landward end can become a blowhole during storms.

Coral paleoclimatology; Geochemical tracers; Proxies

## Definitions

**Coral geochemistry:** The science of studying variations in the stable isotopic composition and trace element impurities in the calcium carbonate of coral skeletal material. The stable isotope and trace element geochemistry of coral carbonate reflects changes in the environmental conditions the coral is living in and/or the physiology of the coral.

**Stable isotope:** Two or more forms of a chemical element that have a different atomic mass. The isotopic forms of a particular element differ in the number of neutrons contained in the atom's nucleus. The term *stable isotope* refers specifically to the isotopic forms of a chemical element that do not undergo radioactive decay.

**Trace element:** Any element that is present in minute quantities, often substituting within a compound or crystal structure for a more abundant element that behaves in a similar fashion chemically.

## Overview

Massive corals in the reef ecosystems of the tropics provide some of the richest paleoclimate archives in the world. Corals are particularly useful paleoclimate recorders because they are widely distributed, can be accurately dated, and contain a remarkable array of geochemical tracers within their calcium carbonate (aragonite) skeletons. The suite of isotopic and elemental tracers in corals presently exceeds that developed for any other biogenic mineral phase. As a result, a multi-proxy approach to coral-based paleoclimatology is emerging that is yielding new insights into tropical paleoclimates (see [Paleoclimate from Corals](#)).

*Porites* is the most widely utilized genus in coral paleoenvironmental studies because it is common throughout the tropical Pacific and Indian Oceans, and individual colonies can live for up to ~400 years (see [Porites](#)). Reconstructions of even greater length are being developed using the longer-living and slower-growing genus, *Diploastrea*. In the Atlantic Ocean, coral reconstructions are commonly extracted from massive colonies of *Montastrea*, and to a lesser extent *Diploria*, which may also live for many centuries. Scleractinian corals from subtropical settings and the deep ocean are also being explored as recorders of environmental conditions (see [Cold Water Coral Reefs](#)). The following discussion will focus on environmental proxies in tropical reef-building corals.

Isotopic and elemental tracers in fossil corals preserved in submerged and tectonically raised reefs (see [Emergent Reefs](#); [Submerged Reefs](#)) offer a unique archive for defining the sensitivity of tropical climate to changing boundary conditions throughout the late Quaternary (the last ~500,000 years). Precise radiometric ages and internal chronologies for coral records are essential for integrating them with other high-resolution paleoclimate data derived from tree rings, ice cores, and varved sediments. Ages for fossil corals may be obtained by measuring U/Th with thermal ionization mass spectrometry (Edwards et al., 1987), with errors generally less than 1% for samples that

Diagenesis is a critical issue for coral paleoenvironmental studies (see *Diagenesis*, *Aragonite* and *Calcite*). Any secondary carbonate material that forms in the coral skeletal structure will alter the original isotopic and trace element signals and compromise the chemical record. To date, the effects of diagenesis have only been studied in detail for the main coral proxies (namely  $^{18}\text{O}/^{16}\text{O}$ ,  $^{13}\text{C}/^{12}\text{C}$ , and Sr/Ca). Overgrowths of inorganic aragonite precipitated from seawater and dissolution of coral aragonite produce cool artifacts in sea-surface temperatures (SSTs) reconstructed from coral  $^{18}\text{O}/^{16}\text{O}$  and Sr/Ca (e.g., Enmar et al., 2000; Müller et al., 2001; Hendy et al., 2007). In subaerial settings, freshwater diagenesis can lead to the precipitation of inorganic calcite within fossil coral skeletons. The relatively high Sr/Ca of calcite produces strong warm artifacts in coral paleotemperature records (McGregor and Gagan, 2003). In contrast, inorganic calcite precipitated from reactions involving tropical meteoric waters generally has an  $^{18}\text{O}/^{16}\text{O}$  composition similar to that found in coral aragonite. Corals can be screened for diagenesis using X-ray diffractometry

**Stable Isotopes and Trace Elements, Table 1** Summary of environmental factors controlling geochemical tracers in coral skeletons

| Tracer                | Environmental signals |                     |                     |                   |    |                     |           |                 |           |
|-----------------------|-----------------------|---------------------|---------------------|-------------------|----|---------------------|-----------|-----------------|-----------|
|                       | Temperature           | Rainfall/<br>Runoff | Light/<br>Turbidity | Ocean circulation | pH | Redox<br>conditions | Nutrients | Nuclear testing | Pollution |
| $\delta^{18}\text{O}$ | X                     | X                   |                     |                   |    |                     |           |                 |           |
| $\delta^{13}\text{C}$ |                       |                     | X                   | X                 |    |                     | X         |                 |           |
| Sr/Ca                 | X                     |                     |                     |                   |    |                     |           |                 |           |
| U/Ca                  | X                     |                     |                     |                   |    |                     |           |                 |           |
| Mg/Ca                 | X                     |                     |                     |                   |    |                     |           |                 |           |
| B/Ca                  | X                     |                     |                     |                   |    |                     |           |                 |           |
| Luminescence          |                       | X                   |                     |                   |    |                     |           |                 |           |
| Ba/Ca                 |                       | X                   |                     | X                 |    |                     | X         |                 |           |
| Cd/Ca                 |                       |                     |                     | X                 |    |                     | X         |                 | X         |
| Mn/Ca                 |                       |                     |                     |                   |    | X                   |           |                 |           |
| REEs                  |                       |                     |                     |                   |    | X                   |           |                 | X         |
| $\Delta^{14}\text{C}$ |                       |                     |                     | X                 |    |                     | X         | X               |           |
| Pb/Ca                 |                       |                     |                     |                   |    |                     |           |                 | X         |
| $\delta^{11}\text{B}$ |                       |                     |                     |                   | X  |                     |           |                 |           |
| P/Ca                  |                       |                     |                     |                   |    |                     | X         |                 | X         |
| $\delta^{15}\text{N}$ |                       |                     |                     |                   |    |                     | X         |                 | X         |

(for calcite), thin section analysis, and scanning electron microscopy (e.g., Bar-Matthews et al., 1993; Hendy et al., 2007; McGregor and Abram, 2008). The use of multiple coral records from similar time periods also serves to reduce potential errors in paleoenvironmental reconstructions (e.g., Hendy et al., 2002).

## Stable isotopes

### Oxygen isotopes

The use of oxygen isotope ratios in carbonate minerals as a paleothermometer began with Urey (1947), who showed that thermodynamic fractionation of  $^{18}\text{O}$  and  $^{16}\text{O}$  occurs during carbonate precipitation. Today, the majority of coral geochemical studies are based on measurements of oxygen isotopes because they are relatively straightforward to measure and interpret. Stable isotope ratios are expressed using a delta notation ( $\delta$ ), where  $\delta$  is the measured heavy isotope enrichment relative to a reference material expressed as a deviation in parts per thousand (‰). The  $\delta$  value for oxygen is defined by the equation  $\delta^{18}\text{O} = 1000(R_s - R_r)/R_r$ , where  $R_s$  and  $R_r$  are the  $^{18}\text{O}/^{16}\text{O}$  ratios of the sample and reference material, respectively. In oxygen isotope studies the term enrichment refers to an increased abundance of the heavier  $^{18}\text{O}$  atom, corresponding to a higher  $\delta^{18}\text{O}$  value.

The  $\delta^{18}\text{O}$  of coral aragonite reflects the temperature and  $\delta^{18}\text{O}$  value of seawater during coral growth. However, the symbiotic algae in the coral tissue enhance calcification rates, thus coral aragonite is depleted in  $^{18}\text{O}$  relative to aragonite precipitated in equilibrium with ambient seawater. McConnaughey (1989a, b) showed that kinetic isotope disequilibrium during the hydration and hydroxylation of  $\text{CO}_2$  produces simultaneous depletions of  $^{18}\text{O}$  and  $^{13}\text{C}$  in coral skeletons. The  $\delta^{18}\text{O}$  disequilibrium offset can differ between coral colonies, resulting in differences of up to 0.4‰ in mean  $\delta^{18}\text{O}$  (e.g., Linsley et al., 1999; Cobb et al., 2003; Felis et al., 2003). Multiple coral samples from similar time periods can be analyzed to reduce the uncertainty in interpreting differences in mean coral  $\delta^{18}\text{O}$  values (e.g., Cobb et al., 2003; Abram et al., 2009).

It appears that the  $\delta^{18}\text{O}$  offset for individual coral colonies generally remains constant over time and does not affect the interpretation of isotopic signals within single coral samples (e.g., McConnaughey, 1989a; Hendy et al., 2002). However, in rare cases where *Porites* coral extension rates are less than  $6 \text{ mm year}^{-1}$ , kinetic disequilibrium does affect coral  $\delta^{18}\text{O}$  (Felis et al., 2003). This growth effect has also been observed within individual coral colonies, where  $\delta^{18}\text{O}$  values tend to be higher on the shaded, slow-growing sides of colonies, or within valley structures (McConnaughey, 1989a; Allison et al., 1996; Cohen and Hart, 1997). Growth effects can be minimized by analyzing corals with extension rates exceeding  $6 \text{ mm year}^{-1}$  and by sampling for  $\delta^{18}\text{O}$  along major coral growth axes.

A common approach in early environmental reconstructions using coral  $\delta^{18}\text{O}$  (when other tracers were not analyzed) was to attribute the source of the isotopic variations primarily to a single factor. For example, at sites where the  $\delta^{18}\text{O}$  of seawater remains approximately constant, coral  $\delta^{18}\text{O}$  records have been used as a proxy for SST based on carbonate paleotemperature relationships (e.g., Epstein et al., 1953; Weber and Woodhead, 1972).  $\delta^{18}\text{O}$ -SST calibrations have been developed for several reef settings where variations in SST dominate changes in coral  $\delta^{18}\text{O}$ . The  $\delta^{18}\text{O}$ -temperature dependence for *Porites* corals is generally from  $-0.18\text{‰}$  to  $-0.22\text{‰}$  per  $1^\circ\text{C}$  (e.g., Weber and Woodhead, 1972; McConnaughey, 1989a; Gagan et al., 1994; Leder et al., 1996; Quinn et al., 1996; Wellington et al., 1996; Gagan et al., 1998; Suzuki et al., 1999; Felis et al., 2000; Juillet-Leclerc and Schmidt, 2001). A recent compilation of 14 coral  $\delta^{18}\text{O}$  records for the tropical Indian and Pacific oceans indicates that the late twentieth century was the warmest period in the tropics over the last 250 years (Wilson et al., 2006).

At other reef locations, changes in the  $\delta^{18}\text{O}$  of seawater override the influence of changes in SST on coral  $\delta^{18}\text{O}$ . Seawater  $\delta^{18}\text{O}$  varies in response to changes in the balance between precipitation, evaporation, and water advection. At sites where seawater  $\delta^{18}\text{O}$  correlates with rainfall, long coral  $\delta^{18}\text{O}$  records have been used to reconstruct precipitation patterns. Such records have been particularly useful for understanding the long-term history of intertropical convergence zone positioning and ENSO rainfall variability (e.g., Cole et al., 1993; Linsley et al., 1994; Tudhope et al., 2001; McGregor and Gagan, 2004).

A more powerful recent approach has been to determine SST variations using an independent coral proxy (such as Sr/Ca) and couple this with coral  $\delta^{18}\text{O}$  measurements to reconstruct both temperature and hydrological variations (e.g., McCulloch et al., 1994; Gagan et al., 1998; Gagan et al., 2000; Ren et al., 2002; Abram et al., 2007). The  $\delta^{18}\text{O}$  residual ( $\Delta\delta^{18}\text{O}$ ), obtained by removing the temperature component of the coral  $\delta^{18}\text{O}$  signal, can be used to make inferences about the hydrological cycle because  $^{18}\text{O}$  is fractionally distilled during the evaporation and precipitation of water vapor between the ocean and atmosphere. Advances in the analytical techniques for measuring trace elements in carbonates has meant that these multi-proxy studies are becoming more common, and there is less reliance on assuming a dominant SST or rainfall driver in interpreting coral  $\delta^{18}\text{O}$  records.

### Carbon isotopes

Carbon isotope ratios ( $\delta^{13}\text{C}$ ; representing  $^{13}\text{C}/^{12}\text{C}$ ) in coral aragonite are measured simultaneously with  $\delta^{18}\text{O}$  during the stable isotope analysis of  $\text{CO}_2$  and a large body of archived  $\delta^{13}\text{C}$  data is available. The interpretation of  $\delta^{13}\text{C}$  records from corals is not straightforward owing to the wide range of factors that modulate coral  $\delta^{13}\text{C}$ . The  $\delta^{13}\text{C}$  of coral aragonite reflects kinetic and metabolic

disequilibrium offsets, as well as variations in seawater isotopic composition (e.g., McConnaughey, 1989a; Swart et al., 1996). Seawater  $\delta^{13}\text{C}$  is controlled by the balance between primary production and respiration in the surrounding ecosystem, by air–sea exchange, and by mixing of surface and upwelled waters. In upwelling regions, nutrient-driven algal blooms can alter coral  $\delta^{13}\text{C}$  by preferentially removing  $^{12}\text{C}$  from seawater (Abram et al., 2003), and by changing the balance between the autotrophic and heterotrophic diet of the coral (Felis et al., 1998).

Coral  $\delta^{13}\text{C}$  is strongly influenced by metabolic fractionation due to coral respiration and endosymbiotic algal photosynthesis (e.g., McConnaughey, 1989b; Grottoli and Wellington, 1999). Endosymbiotic photosynthesis is generally the dominant influence on skeletal  $\delta^{13}\text{C}$  in hermatypic corals like *Porites* (McConnaughey et al., 1997). Photosynthesis depends to a large extent on ambient light levels, mediated by insolation, coral depth, and water column turbidity (e.g., Swart, 1983). At many sites, the seasonal cycle of cloudiness is in phase with coral  $\delta^{13}\text{C}$  cycles, with decreased photosynthesis leading to depletion of  $^{13}\text{C}$  in the coral skeleton (e.g., Goreau, 1977; Fairbanks and Dodge, 1979; McConnaughey, 1989a, b; Cole and Fairbanks, 1990; Winter et al., 1991; Shen et al., 1992). A decrease in skeletal  $\delta^{13}\text{C}$  also occurs in corals at increasing water depth, related to decreased light intensity and photosynthesis (e.g., Weber et al., 1976; Grottoli and Wellington, 1999). The metabolic influence associated with the annual coral spawning process has also been shown to produce distinct, short-lived  $^{13}\text{C}$  enrichments in coral  $\delta^{13}\text{C}$  records (Gagan et al., 1996).

### Minor and trace elements

Studies of trace elements in corals have generally focused on elements that substitute for calcium in the aragonite crystal lattice, and the amount of trace element is usually expressed as an element/Ca ratio. The most studied elements in coral aragonite are divalent cations that are abundant in seawater (i.e., Mg, Sr, U, Ba, and B) and have chemical properties similar to calcium. Less-abundant divalent cations occur in trace abundances ( $<1$  nmol/mol Ca – 1  $\mu\text{mol/mol}$  Ca) in corals. In some cases, trace elements may be adsorbed on the coral skeletal surface or concentrated in occluded organic matter. Therefore, in general thorough cleaning of coral samples is required to remove trace elements that are not incorporated into the aragonite lattice to avoid artifacts in environmental reconstructions (e.g., Shen et al., 1987; Fallon et al., 1999).

Many of the trace element proxies discussed below are still being developed and the systematics of their incorporation in coral aragonite requires further testing before they can be considered robust indicators of environmental conditions. The following section summarizes the most common trace elements studied in corals, broadly separated under three headings on the topics of paleothermometry, ocean–atmosphere–land interactions, and human impacts on the marine environment.

### Paleothermometry

Trace elements in coral skeletons are most commonly used as a proxy for ocean temperature. Strontium/calcium (Sr/Ca) in coral aragonite is the most established and reliable paleothermometer. Early studies indicated that there was a small inverse relationship ( $\sim 1\%$  decrease in Sr/Ca per  $^{\circ}\text{C}$ ) between SST and coral Sr/Ca (Weber, 1973; Smith et al., 1979). In a breakthrough study, Beck et al. (1992) used precise isotope dilution thermal ionization mass spectrometry to establish a  $0.6\%$  decrease in Sr/Ca per  $^{\circ}\text{C}$  with analytical precision equating to  $\pm 0.05^{\circ}\text{C}$ . Since then, coral Sr/Ca–SST calibrations have been developed for a wide range of reef sites around the Pacific and Indian Oceans (e.g., McCulloch et al., 1994; Shen et al., 1996; Alibert and McCulloch, 1997; Gagan et al., 1998; Marshall and McCulloch, 2002). A review of 38 published Sr/Ca–SST relationships for *Porites* corals found that the mean Sr/Ca–SST dependence is  $0.061$  mmol/mol per  $^{\circ}\text{C}$  (Corrège, 2006).

A primary assumption in coral Sr/Ca paleothermometry is that biological effects on coral Sr/Ca are negligible, leaving SST as the primary factor controlling Sr uptake. While coral growth rate and algal symbiont photosynthesis have a marked influence on coral Sr/Ca (e.g., Cohen et al., 2001), it has been shown that biological effects are usually only significant at low coral growth rates, or where geochemical sampling is not made along a major coral growth axis (de Villiers et al., 1994; de Villiers et al., 1995; Alibert and McCulloch, 1997; Gagan et al., 1998; Mitsuguchi et al., 2003). Nevertheless, there are, in some cases, significant differences between the intercepts of individual Sr/Ca–SST calibration equations and the source of these offsets is yet to be fully understood. Some of the offsets may be explained by slight differences in seawater Sr/Ca between different regions (de Villiers, 1999), or by differences between the temperature of the coral microenvironment and the SST records used to calibrate coral Sr/Ca. It has also been suggested that the influence of light levels on coral calcification and Sr uptake (Cohen et al., 2001) could explain some differences in coral Sr/Ca–SST calibrations (Gagan et al., 2004). As for coral  $\delta^{18}\text{O}$ , the potential for Sr/Ca offsets between coral colonies means that reliable records of mean SST can only be derived using a large number of corals of similar age (e.g., Hendy et al., 2002; Abram et al., 2009).

The other fundamental assumption used in coral Sr/Ca thermometry is that the Sr/Ca composition of seawater has remained constant through time. Given the long oceanic residence time of Sr (2.5 million years) and Ca (0.6–1.1 million years), this assumption was thought to be valid over glacial-interglacial timescales. However, it has been proposed that the concentration of Sr in seawater may increase during glacial episodes due to weathering of shelf carbonates during sea-level lowstands (Stoll and Schrag, 1998). This sea-level-related effect has the potential to produce cool artifacts of up to  $1.5^{\circ}\text{C}$  in fossil coral Sr/Ca records. Also, it has been shown that Sr/Ca in

surface seawater is greater where intense upwelling brings Sr-enriched water to the surface. Again, not accounting for this process can result in overestimation of SST cooling from coral Sr/Ca records (de Villiers, 1999).

To date, Sr/Ca in modern and fossil corals preserved in submerged and tectonically raised reefs has been used to great effect to document the sensitivity of tropical climate to changing boundary conditions throughout the late Quaternary (see *Paleoclimate from Corals*). In addition to Sr/Ca, precise measurements of uranium/calcium (U/Ca) and magnesium/calcium (Mg/Ca) in corals have provided useful paleothermometers (Min et al., 1995; Shen and Dunbar, 1995; Mitsuguchi et al., 1996). The improved sensitivity of inductively coupled plasma mass spectrometry has led to an increase in the speed and range of trace elements (e.g., B/Ca) that can be measured to examine thermal variations in the tropics (e.g., Sinclair et al., 1998; Fallon et al., 1999; Hendy et al., 2002). The U/Ca, Mg/Ca, and B/Ca SST proxies show higher variability between sites and corals, and so are generally considered less reliable for SST reconstructions than Sr/Ca (Fallon et al., 2003). They are, however, useful additional tracers for verifying SST changes identified by coral Sr/Ca.

## Ocean–atmosphere–land interactions

### *Ultraviolet luminescence*

Luminescent banding, also known as fluorescent banding, can be observed in *Porites* corals from areas that are influenced by river runoff, and was first described by Isdale (1984). Luminescence in coral aragonite occurs under ultraviolet light and is caused by marine fulvic acids (“blue” under ultraviolet light) and terrestrial fulvic and humic acids (“yellow-green”) of relatively low molecular mass in the coral skeleton. These compounds are often seen as distinct bands in corals and it is hypothesized that increased luminescence marks the influx of fulvic acids into seawater during terrestrial runoff events (Boto and Isdale, 1985). An alternate theory is that luminescent bands are the result of reduced coral calcification in response to the low salinity produced by runoff events (Barnes and Taylor, 2001).

The use of coral luminescent banding to reconstruct river runoff has been particularly successful in the Great Barrier Reef, Australia, where Isdale (1984) found a good correspondence between the timing, width, and intensity of luminescent bands in nearshore corals and historical flood events of the Burdekin River. Lough (1991) demonstrated the statistical validity of the luminescence record for reconstructing past rainfall variations over much of northeast Australia. The Great Barrier Reef coral luminescence record has since been developed as a chronological tool for cross-dating between corals (Hendy et al., 2003) and as a proxy for ENSO-related variability of river flow (Lough, 2007). Beyond the Great Barrier Reef, the development of quantitative transfer functions relating luminescent banding to climatic parameters has been hindered by lack of knowledge about the

production rates and exact sources of humic and fulvic acids, as well as the mechanism (i.e., passive or active) for their uptake into the coral skeleton. However, a study of luminescence in last interglacial fossil corals from the Red Sea showed that fluorescence can persist for tens of thousands of years, and suggests that runoff to the Red Sea was greater during the last interglacial (Klein et al., 1990).

### *Barium and cadmium*

Barium/calcium (Ba/Ca) appears to be a conservative tracer that is incorporated into coral aragonite in proportion to its concentration in ambient seawater. Changes in the Ba content of seawater can be related to the upwelling of nutrient-rich (Ba-rich) subsurface water. Given that Ba has a nutrient-like distribution in the water column, Ba/Ca in corals from outer barrier reef locations or upwelling zones has been shown to reflect the intensity of ocean upwelling (Lea et al., 1989). Similarly, coral Cd/Ca has been proposed as a proxy for upwelling intensity and productivity (Shen et al., 1987). However, despite early studies demonstrating a link between ocean upwelling and coral Ba/Ca and Cd/Ca ratios, the practical application of these tracers has been somewhat limited (Reuer et al., 2003; Montaggioni et al., 2006; Alibert and Kinsley, 2008). A recent assessment of coral Cd/Ca records using multiple corals from the Gulf of Panama suggests that several individual records are required to reliably reconstruct ocean upwelling (Matthews et al., 2008).

In nearshore reef settings of the Great Barrier Reef and Kenya, coral Ba/Ca records have been interpreted as proxies for riverine sediment flux (McCulloch et al., 2003; Fleitmann et al., 2007). The coincidence of Ba/Ca peaks with luminescent bands in these nearshore coral records is used as evidence that the Ba is derived from sediments incorporated in river flow. Both records document dramatic increases in soil erosion related to European settlement and changes in land usage. Also, it has been shown that Great Barrier Reef runoff influences the concentration of manganese and rare earth elements in nearshore seawater, and that the combined use of these elements with Ba/Ca can enhance the interpretation of changes in riverine sediment flux (Wyndham et al., 2004; Lewis et al., 2007).

### *Manganese and rare earth elements*

Manganese (Mn) and rare earth elements (REEs) are incorporated into coral skeletons in close proportion to their concentrations in seawater and are potentially useful proxies for biological activity and redox conditions in the water column (Shen et al., 1991; Sholkovitz and Shen, 1995; Wyndham et al., 2004). Seasonal cycles can be observed in the concentration of Mn and REEs in coral skeletons, and in the relative proportion of light to heavy REEs. It has been proposed that this cyclicity reflects a seasonal control on the dissolution of Mn-oxide particles (and associated adsorbed REEs). The dissolution of Mn-oxide may be caused by insolation-driven increases in photoreduction in spring and/or by reducing conditions

resulting from the decay of organic matter produced by spring algal blooms (Alibert et al., 2003; Fallon et al., 2003). At Tarawa atoll, in the central equatorial Pacific, increases in coral Mn during El Niño events have been attributed to wind-driven sediment resuspension allowing Mn to be released to the water column (Shen et al., 1992). Distinct increases in coral Mn and REEs have also been used as evidence for anoxic conditions that resulted in widespread reef death following a large red-tide algal bloom in Indonesia (Abram et al., 2003).

## Human impacts on the marine environment

### *Radiocarbon and nuclear weapons testing*

Nuclear weapons testing in the 1950s produced excess radiocarbon ( $^{14}\text{C}$ ) in the atmosphere, and the oceanic uptake of some of this  $^{14}\text{C}$  has increased the contrast between surface and deep ocean  $^{14}\text{C}$  concentrations.  $^{14}\text{C}$  in coral aragonite tracks  $^{14}\text{C}$  concentrations in the dissolved inorganic carbon of surface seawater. The increase in bomb-produced  $^{14}\text{C}$  in the surface ocean was first measured in *Diploria* and *Montastrea* corals from the Atlantic (Druffel and Linnick, 1978; Nozaki et al., 1978). Since then, several studies have documented differences in the timing and amplitude of the  $^{14}\text{C}$  “bomb-spike” in coral records to study air–sea exchange processes, the mixing of bomb  $^{14}\text{CO}_2$  between the surface mixed layer and upper ocean, and ocean circulation in the tropics (e.g., Druffel, 1987; Toggweiler et al., 1991; Brown et al., 1993; Moore, 1997; Guilderson et al., 1998; Grunet et al., 2004). Coral  $^{14}\text{C}$  records play an important role in providing boundary constraints used to test the parameterization of ocean dynamics in ocean circulation models (e.g., Rodgers et al., 1997).

The oceanic signature of the relatively small reduction of  $^{14}\text{C}/^{12}\text{C}$  in atmospheric  $\text{CO}_2$  produced by the Suess effect has been much more difficult to discern in coral records. The Suess effect is due mainly to the input of  $^{14}\text{C}$ -free  $\text{CO}_2$  from fossil fuel burning into the atmosphere and ocean since ~AD 1850. Variations in surface-ocean  $^{14}\text{C}/^{12}\text{C}$  on century-decade time scales mask the Suess effect in coral records, but provide information on vertical mixing, ocean circulation, and redistribution of surface-waters associated with ENSO (e.g., Toggweiler et al., 1991; Druffel and Griffin, 1993; Guilderson and Schrag, 1998).

### *Lead, cadmium, and industrial pollution*

Lead (Pb) and cadmium (Cd) in coral skeletons record local and global inputs of industrial heavy metal pollution to the oceans (e.g., Shen and Boyle, 1987; Shen et al., 1987; Shen and Boyle, 1988). An important study by this group measured Pb/Ca and Cd/Ca in a Bermuda coral to show that atmospheric fluxes of industrial pollution reached the western North Atlantic from the continental USA via the westerlies. Peaks in Pb/Ca in the coral correlated with the use of tetraethyl lead in automobile gasoline. The initial rise in Cd from 1900 to 1925 was coincident with a rise in zinc production (from which Cd

is a byproduct) that occurred at a time when flue dust recovery was negligible. Similarly, measurements of Pb/Ca in corals from the western Pacific and adjacent seas showed a clear pattern of atmospheric Pb transport from the Asian continent to the open ocean since the late nineteenth century (Inoue et al., 2006).

### *Boron isotopes and seawater pH*

Reconstructing the recent trend and natural variability of ocean pH is crucial to understand the possible consequences of ocean acidification on marine ecosystems due to the absorption of anthropogenic  $\text{CO}_2$  by seawater. Culturing experiments on *Porites* and *Acropora* corals have confirmed that boron isotopes ( $\delta^{11}\text{B}$ ) in coral skeletons faithfully record variations in seawater pH (e.g., Hönisch et al., 2004; Reynaud et al., 2004). The calibration of  $\delta^{11}\text{B}$  with seawater pH for *Porites* is in good agreement with the theoretical curve for the borate species (Hönisch et al., 2004), the major form in which B is incorporated into coral skeletons. However, there is still uncertainty about how biological modulation of B uptake associated with coral calcification may influence paleo-pH records (Gaillardet and Allégre, 1995).

To date, two multi-century records of seawater pH from  $\delta^{11}\text{B}$  have been determined for *Porites* corals, one from Flinders Reef in the Coral Sea (Pelejero et al., 2005) and the other from the central Great Barrier Reef (Wei et al., 2009). The Flinders coral  $\delta^{11}\text{B}$  record, commencing in AD 1708, shows large variations in pH over ~50-year cycles that covary with the Interdecadal Pacific Oscillation. The results indicate that locally significant natural cycles in reef pH can modulate the impact of ocean acidification on coral reef ecosystems. The Great Barrier Reef coral  $\delta^{11}\text{B}$  record, spanning AD 1800–2004, shows an overall trend of ocean acidification with pH decreasing by 0.2–0.3 units since ~1940. The result suggests that increasing levels of atmospheric  $\text{CO}_2$  have already caused significant acidification of the ocean surface.

### *Phosphorous, nitrogen, trace elements, and reef pollution*

Phosphorous (P) and nitrogen isotopes ( $\delta^{15}\text{N}$ ) in corals have been used to reconstruct the history of sewage and agricultural pollution in nearshore reef settings. Phosphate acts as a crystal poison of calcification and Dodge et al. (1984) showed that concentrations of P in corals from the North Atlantic are consistent with the local sewage and pollution history. In principle, the  $\delta^{15}\text{N}$  of residual organic nitrogen in coral skeletons should reflect temporal changes in the balance between natural and anthropogenic nitrogen sources in coastal reef waters. Synthetic nitrogenous fertilizers are typically depleted in  $^{15}\text{N}$  relative to the inorganic nitrogen dissolved in seawater. This technique has been used to show that Western-style agricultural practices since 1970 have contributed to the degradation of coastal reefs in Bali, Indonesia (Marion et al., 2005).

Other trace metals in corals have been shown to be good tracers of pollutants in coral reef environments (e.g., Howard and Brown, 1987; Scott, 1990; Guzman and Jimenez,

1992; Guzman and Jarvis, 1996). A recent study showed that REE (Y, La, Ce), Zn, and Pb concentrations increased significantly in *Porites* corals from Misima Island, Papua New Guinea following the commencement of open-cut gold mining at Misima in 1989 (Fallon et al., 2002).

## Summary

The stable isotopic and trace element compositions of coral skeletons provide a wealth of information about past environmental conditions in reef settings. Interpretation of existing proxies continues to be refined, while the development of new proxies is shedding light on a range of environmental parameters. As the number of stable isotopic and trace element records grows, it is becoming increasingly important to view coral records in spatial networks to enhance the climatic interpretations that can be drawn from them. An important aspect of this involves archiving the geochemical data (and appropriate metadata) derived from corals. We refer readers to the NOAA Climatic Data Center Paleoclimatology website (<http://www.ncdc.noaa.gov/paleo/corals.html>), which is the premier data archive for scientists interested in understanding natural climate variability and future climate change.

## STEERS, JAMES ALFRED (1899 – 1987)

---

Tom Spencer  
 University of Cambridge, Cambridge, UK

(James) Alfred Steers (1899 – 1987), coastal physiographer and early promoter of coastal zone planning and coastal conservation. His entire academic career was spent in the Department of Geography, University of Cambridge, England, entering the Department as an

**Steers, James Alfred (1899 – 1987), Figure 1** Steers and surficial geomorphology of the Great Barrier Reef. The Second International Coral Reef Symposium, held in 1973, was a remarkable undertaking, involving steaming north from Brisbane to Lizard Island and back on a cruise liner, the MV Marco Polo. On board were two members of the 1928–1929 Expedition, Maurice Yonge and Alfred Steers. The meeting coincided with the Royal Society – Universities of Queensland Expedition to the northern Great Barrier Reef, led by David Stoddart. Here Alfred Steers (*far left*), Richard Orme (*second left*, 1973 Expedition member), David Stoddart (*back to camera*) and other symposium participants discuss the shingle rampart features at Low Isles (photograph: David Hopley).

undergraduate in 1916 and retiring as Professor of Geography in 1966. He was the senior member of the Geographical Section of the Great Barrier Reef Expedition to Low Isles 1928–1929, led by C. M. Yonge, where he was involved in regional survey and detailed island mapping of the “low wooded islands” of Low Isles and Three Isles with M. Spender. Fieldwork on the Reef led to early speculations on regional tectonics, sea-level change and reef island development and this was followed by a second expedition in 1936 when reef islands were extensively mapped between 24°S (Bunker and Capricorn Groups) and 13°S (Cape Direction). Steers subsequently encouraged reef mapping on the Great Barrier Reef using aerial photography and was a member of the planning committee that resulted in the Royal Society of London and Universities of Queensland Expedition to the northern Great Barrier Reef in 1973, led by D. R. Stoddart (Figure 1). In 1939, Steers participated in an expedition to Jamaica (leader: V. J. Chapman; mapping of Port Royal Cays, Morant Bank cays, Palisadoes spit) which was curtailed by the outbreak of World War II. In 1977, with Stoddart, he published two synthesis papers on the origin of fringing reefs, barrier reefs and atolls and on the typology and origin of reef islands.

science and organizer of international reef science from the Department of Geography, University of Cambridge, England 1956–1988 (pupil of J.A. Steers; PhD on the Belize Barrier Reef, 1964); thereafter Professor of Geography, University of California at Berkeley. Significant contributions to the modern description and re-description of reef landforms in all the major reef provinces, characterized by careful field observations (including detailed surface mapping), use of the comparative method, and an ability to consider the interplay of the different time and spatial scales of controlling processes, including an appreciation of environmental variability and the role of extreme events. Stoddart has made major contributions to the understanding of tectonics and sea level dynamics on Pleistocene, Holocene, and historical time scales and their implications for coral reef geomorphology and ecology; to ocean basin biogeography; to coral island floristics and ecology; and to the history of coral reef science. He has also made notable contributions to coral reef conservation, most particularly in the saving of Aldabra Atoll, S.W. Indian Ocean for science. He was the key energizer of the international coral reef symposia, a member of the Editorial Board of the Atoll Research Bulletin since 1969, a founding member and initiator of the International Society for Reef Studies, its first President, and subsequently coordinating editor of the journal ‘Coral Reefs’.

## STROMATOLITES

R. Pamela Reid  
University of Miami, Miami, FL, USA

### Synonyms

Laminated microbialites (see Chapter *Microbialites*)

### Definition

Stromatolites are lithified laminated organosedimentary deposits produced by the sediment trapping, binding, and/or precipitation activities of microbial communities dominated by photosynthetic bacteria (modified from Awramik, 1992).

### Introduction

Stromatolites are Earth's earliest and most persistent reefs. They are conspicuous and widespread components of Precambrian carbonate platforms and are still forming in modern environments (Figure 1). Despite over a 100 years

**Stromatolites, Figure 1** Ancient and modern stromatolites. (a) Archean stromatolites on shallow platforms fringing volcanoes; painting by P. Sawyer, reprinted with permission from Natural History Museum, Smithsonian Institution. (b) Modern stromatolites on the margins of Hamelin Pool, Shark Bay, Western Australia.

of research, the significance, origin, and very definition of stromatolites are, however, still disputed (Semikhatov et al., 1979; Ginsburg, 1991; Grotzinger and Knoll, 1999; Riding, 1999; Awramik and Grey, 2005; Schopf, 2006).

Derived from the Greek “stroma,” meaning mattress or stratum, and “lithos,” meaning rock, the term stromatolite was introduced by Kalkowsky (1908) to refer to “organogenic, laminated calcareous rock structures, the origin of which is clearly related to microscopic life, which in itself must not be fossilized” (translated in Krumbein, 1983, p. 499). This definition requires that “microbial influence be interpretable from features of lamination and texture in the absence of direct paleontologic evidence for mat organisms” (Grotzinger and Knoll, 1999, p. 316). With such ambiguity, there is major disagreement as to whether the definition of stromatolite should be genetic or purely descriptive (see for example, Krumbein, 1983; Grotzinger and Knoll, 1999; Riding, 1999). An often used non-genetic definition is that a stromatolite is an “attached laminated lithified sedimentary growth structure, accretionary away from a point or limited surface of initiation” (Semikhatov et al., 1979). This purely descriptive definition allows for terms, such as “abiogenic stromatolite,” which, it could be argued, corrupt the original intent of the term (Awramik and Grey, 2005).

In this review, the term stromatolite is used in the traditional sense of Kalkowsky for lithified, laminated sedimentary structures formed as a result of microbe–sediment interactions. As such, stromatolites are a subset of microbialites, a term coined by Burne and Moore (1987) to include all organosedimentary deposits that have accreted as a result of benthic microbial communities trapping and binding sediment and/or forming the locus of mineral precipitation. Stromatolites are differentiated from other types of microbialites, such as thrombolites (with clotted textures), by their layered internal structure.

Dominating the fossil record for 80% of Earth history, stromatolites are potentially a major source of information on the early Biosphere (Awramik, 1992; Walter, 1994). Scientists believe, moreover, that the photosynthetic activity of cyanobacteria (formerly known as blue-green algae and commonly regarded as the most important group of stromatolite-forming microorganisms) generated the oxygen of our atmosphere (Schopf et al., 1983). An oxygen-rich atmosphere was critical to the development of higher forms of life on Earth.

Described at a variety of scales, stromatolites form ridges and bioherms composed of individual buildups with shapes ranging from simple domes to elaborately branched columns. Millimeter-scale lamination, visible with the naked eye, shows diverse microstructures when viewed in petrographic thin section. Variations in stromatolite structures, from megascale to microscale features, reflect the interaction of biological and geological activities on an evolving Earth.

## Stromatolites on early Earth

The fossil record of stromatolites spans more than three billion years, dating back to the Archean. Precambrian stromatolites constructed impressive reef complexes, rivaling any in later periods. Individual stromatolites are the “framebuilding” constituents of Precambrian reefs—analogs to the calcified metazoans of Phanerozoic reefs. The overall geometry and growth morphology of Precambrian reefs was a function of platform position and is similar to the distribution of metazoan reefs on Phanerozoic platforms. This illustrates the universal importance of bioherms in carbonate facies development, regardless of reef-building organisms (James and Geldsetzer, 1988; Aitken, 1988).

The first stromatolites occur in the Early Archean (3.8–3.3 billion years ago). Although the Early Archean was dominated by active tectonism and volcanism, small isolated carbonate platforms with stromatolites formed during brief quiescent periods. Despite reports questioning the biogenicity of Early Archean stromatolites (e.g., Lowe, 1994; Brasier et al., 2004), there is compelling evidence that these ancient structures are products of mat-building communities (Schopf, 2006; Awramik, 2006). Stromatolites in the Strelly Pool Chert in Western Australia, for example, are unusually well preserved and morphologically diverse (Allwood et al., 2006, 2007). These stromatolites formed in shallow marine environments with low rates of terrigenous sedimentation and no direct input from high temperature hydrothermal systems; the compositions and textures of the stromatolites are indicative of microbially influenced sedimentation (Allwood et al., 2006, 2007). The remarkable Strelly Pool Chert stromatolites thus provide “ecosystem-scale insights into early life on Earth” (Allwood et al., 2007, p. 198).

With the gradual development of stable continents during the Middle and Late Archean (3.3–2.5 billion years ago), carbonate platforms and stromatolites became increasingly common. One of the best known Late Archean examples is the stromatolite-rimmed Campbellrand carbonate belt of South Africa, which is more than 1.5 km thick (Grotzinger, 1994). Full development of large continents with spacious shallow water platforms allowed extensive development of stromatolite reef systems on a global-scale during the Proterozoic (2.5–0.5 billion years ago; Figure 2). Early Proterozoic stromatolite barrier reefs in Canada, for example, attained thicknesses of 1 km and lengths of 600 km (Hoffman, 1988; Hoffman and Grotzinger, 1988). During Early and Middle Proterozoic time, high energy reef margins were characterized by belts of strongly elongated stromatolitic mounds, with isolated domes in protected inner shelf environments and stromatolitic pinnacle reefs on deep water ramps.

The widespread occurrence of stromatolites on Precambrian platforms had major implications for carbonate budgets. Stromatolites were not only depositories, but were

also factories for carbonate production, with microbial activities inducing precipitation of carbonate within the stromatolitic mats, and/or in the water column above the stromatolites (Grotzinger, 1988). There were, moreover, notable changes in the style and mode of stromatolite accretion throughout the Precambrian, with precipitation dominating in Archean stromatolites, trapping and binding of micrite (fine grained carbonate,  $<4\ \mu\text{m}$ ) dominating in Late Proterozoic stromatolites, and both modes of accretion in the intervening periods (Grotzinger, 1994). To add to this complexity, inorganic seafloor precipitation was ubiquitous on Late Archean platforms, and may have formed layered domal structures that mimic stromatolites (Sumner and Grotzinger, 2000).

## Stromatolite decline

After reaching a peak in abundance and diversity during the Proterozoic, stromatolites subsequently declined. The exact timing of the decline remains a subject of debate, reflecting differing computational methods (Grotzinger and Knoll, 1999; Riding, 2006). The most recent estimates of the commencement of decline range from 1,250 to 700 million years ago (Walter et al., 1992; Awramik and

**Stromatolites, Figure 2** One billion year-old stromatolites in the Atar group, Mauritania, West Africa. (a) Meter-scale patch reefs. (b) Fine scale lamination in radiating columns of the stromatolite *Tungussia confusa*.

Sprinkle, 1999; Riding 2006). Reasons for the decline are similarly controversial, and include diversification and radiation of seaweeds capable of outcompeting microbial mats for space on the seafloor (Fischer, 1965; Monty 1973; Knoll and Swett, 1990; Grotzinger and Knoll, 1999), changes in seawater chemistry (Grotzinger, 1990; Fischer, 1965), and grazing, burrowing, and competition for space by metazoans (Awramik, 1971; Garrett, 1970; Walter and Heys, 1985).

Stromatolites show marked fluctuations throughout the Phanerozoic (Pratt, 1982; Riding, 2006). They are common features of Cambrian and Lower Ordovician platforms, although the first sessile metazoans began to share reef construction, with archeocyathids in Lower Cambrian reefs and corals and sponges in Lower Ordovician reefs. Stromatolites declined markedly with major diversification of reef-building metazoans in Middle Ordovician, although microbial buildups remained locally important (Pratt, 1982). Stromatolites showed a resurgence during the Late-Devonian–Early Mississippian, and again in the Early Triassic, giving rise to the concept that they are “disaster biotas” (Schubert and Bottjer, 1992), thriving in the aftermath of mass extinctions, when competition from eukaryotic plants and animals was greatly reduced. Stromatolites were generally scarce during the Cenozoic.

### Modern stromatolites

For years, living stromatolites were thought to be extinct. Then, in the 1960s, modern stromatolites were found in Shark Bay, Western Australia, where the seawater is too salty for most animals and plants to survive (Figure 1b; Logan, 1961; Playford and Cockbain, 1976). Since the Shark Bay discovery, stromatolites have been found in a wide variety of modern environments, including saline lakes in Australia (e.g., Lake Thetis and lakes on Rottnest Island; Reitner et al., 1996); hypersaline lakes on Bahamian islands (e.g., Storr’s Lake on San Salvador; Mann and Nelson, 1989; Neumann et al., 1988), a brackish water lagoon in Belize (Chetumal Bay, Rasmussen et al., 1993), fresh water lakes in Antarctica (Parker et al., 1981), alkaline lakes in Tonga (e.g., Caldera lakes of Niuafo’ou Island; Kazmierczak and Kempe, 2006), and continental or subaerial settings (e.g., Verrecchia et al., 1995). In these examples, local development of harsh environmental conditions excludes most eukaryotes and allows stromatolite-building microorganisms to become the dominant community.

The first modern stromatolites growing in open marine conditions were discovered in Schooner Cays, Bahamas in the early 1980s (Dravis, 1983). Additional occurrences of open marine stromatolites have since been found at several additional localities along the margins of Exuma Sound, Bahamas, including Lee Stocking Is., Stocking Island, Highborne Cay, and Little Darby Island (Figure 3a) (Dill et al., 1986; Reid et al., 1995). As the only known examples of modern stromatolites forming in open marine environments similar to those of

Precambrian carbonate platforms, Exuma stromatolites have been a subject of intense investigation for the past decade (e.g., Stolz et al., 2009; Dupraz et al., 2009; Baumgartner et al., 2006, 2009; Decho et al., 2009; Foster et al., 2009; Desnues et al., 2008; Eckman et al., 2008; Visscher and Stolz 2005; Reid et al., 2000; Visscher et al., 2000; and additional publications listed at <http://www.stromatolites.info>). These studies serve as a basis for studying stromatolite morphogenesis and investigating factors leading to a dominance of microbes vs. metazoans as dominant reef builders (e.g., Reid et al., 2000; Andres and Reid, 2006; Andres et al., 2009).

Exuma stromatolites form as columns and ridges, ranging in height from several centimeters to 2 m. Millimeter-scale lamination in these stromatolites is visible in cut sections as alternations of hard and soft layers (Figure 3c; Reid et al., 1995). The soft layers, which are 1–2 mm thick, are composed primarily of unconsolidated fine-grained carbonate sand with average grain size of 125–250  $\mu\text{m}$ . There are two types of hard layers, which stand out in relief on the cut sections: (1) thin crusts of micrite, 20–50  $\mu\text{m}$  thick, and (2) cemented layers of fused carbonate sand grains, 1–2 mm thick.

A model for the formation of laminae in Exuma stromatolites was developed on the basis of integrated studies relating subsurface microstructure to microbial populations on the surfaces of the stromatolites (Reid et al., 2000). Three surface “mat types,” each characterized by a distinct community are recognized (Figure 3b): Type 1 mats are characterized by a filamentous cyanobacterial community; Type 2 mats are a biofilm community dominated by heterotrophic bacteria; and Type 3 mats are characterized by an abundance of endolithic coccoid cyanobacteria. Each surface community is associated with the accretion of a distinct type of mineral deposit (Figure 3c): Type 1 filamentous cyanobacterial mats accrete unconsolidated layers of trapped and bound sand grains; Type 2 biofilms precipitate micritic crusts (Visscher et al., 1998, 2000); and coccoid endoliths of the Type 3 mats form cemented layers of fused microbored (micritized) grains (Macintyre et al., 2000). Stromatolite lamination results from a cycling of the three surface mats, with each subsurface layer representing a community that was, at one time, at the stromatolite surface (Figure 3c). It is important to note that lamination in stromatolites is fundamentally different from lamination in microbial mats. Lamination in microbial mats results from community stratification due to gradients in light intensity, whereas lamination in stromatolites results from interactions of mats with depositing sediment and/or precipitating minerals (Grotzinger and Knoll, 1999, p. 324).

As a result of the sandy textures of marine Bahamian stromatolites, some authors have proposed that these coarse grained structures, as well as similar sandy stromatolites in Shark Bay, are not appropriate analogs for fossil stromatolites, which are typically composed of micrite (e.g., Awramik and Riding, 1988). It has further been proposed that the differences in grain size reflect an evolution

**Stromatolites, Figure 3** Modern marine stromatolites from Exuma Cays, Bahamas. (a) Underwater photograph of columnar stromatolites about 40 cm high, Little Darby Island (b) Surface communities. B<sub>1,2</sub> – Type 1 mats; filamentous cyanobacteria (arrows) bind carbonate sand grains. B<sub>3,4,5</sub> – Type 2 biofilm; a continuous sheet of exopolymer with abundant heterotrophs drapes the surface, aragonite needles (B<sub>5</sub>) precipitate in this biofilm. B<sub>6,7,8</sub> – Type 3 mats; a surface biofilm overlies filamentous cyanobacteria and endolith infested grains, which appear gray and are fused. Banded pattern of fibrous aragonite in bore holes (B<sub>7</sub>) indicates progressive infilling. Precipitation in tunnels that cross between grains leads to fusion (B<sub>8</sub>) (c) Subsurface layers. C<sub>1</sub> – vertical cut section shows mm-scale lamination resulting from an alternation of hard and soft layers. C<sub>2</sub> – low magnification thin section photomicrograph of boxed area in C<sub>1</sub> showing the distribution of lithified layers (black and white lines). C<sub>3</sub> – micritic crust, equivalent to the black lines in C<sub>2</sub>. C<sub>4</sub> – layer of microbored fused grains, equivalent to the white lines in C<sub>2</sub>, underlying a micritic crust. Modified from Reid et al. (2003).

of stromatolite-building communities, from Precambrian prokaryotic communities, which trap, bind, and precipitate micrite, to Cenozoic communities that include macro and microalgae, in particular diatoms, which accrete sand (Awramik and Riding, 1988; Riding, 2000). Detailed growth studies of Bahamian stromatolites show, however, that modern marine sandy stromatolites can be accreted by purely prokaryotic communities (Reid et al., 2000). Moreover, the ecological model developed for Bahamian stromatolites, in which lamination results from the cycling of prokaryotic communities on stromatolites surfaces, may be applicable to other modern and fossil stromatolites. Of particular interest is precipitation of micritic crusts by the Type 2 biofilm community, as these crusts resemble micritic crusts in fossil stromatolites.

Precipitation of calcium carbonate in stromatolites is commonly linked to photosynthesis, resulting from an increase in alkalinity triggered by the uptake of  $\text{CO}_2$  by cyanobacteria (Pentecost and Riding, 1986; Arp et al., 2001; Aloisi, 2008). Although autotrophic primary production by cyanobacteria is of key importance in stromatolite mats, producing sticky exopolymeric substances (EPS), other microbial groups can play key roles in increasing carbonate saturation (Visscher and Stolz, 2005; Dupraz and Visscher, 2005; Dupraz et al., 2009). Indeed, micrometer-scale mapping of microbial activities in Exuma stromatolites shows correlations between carbonate precipitation in Type 2 biofilms and high rates of sulfate-reduction (Visscher et al., 1998, 2000). Precipitation of micritic crusts in these biofilms is attributed to an increase in alkalinity resulting from sulfate reduction and  $\text{Ca}^{2+}$  release from degraded EPS (Visscher et al., 1998, 2000; Reid et al., 2000). The result is precipitation of a thin crust of aragonite with an isotopic signature that confirms the role of sulfate reducing bacteria (Andres et al., 2006). Various microbial metabolisms driving the “alkalinity engine,” together with the exopolymeric matrix, are recognized as fundamental controls of carbonate precipitation in microbial mats (Dupraz et al., 2009).

Finally, living stromatolites in the back reef lagoons of coralline algal fringing reef complexes at Stocking Island and Highborne Cay, Bahamas, provide insight into controls governing the spatial distribution of microbial vs. metazoan reef builders in a modern setting (Andres et al., 2009). The reefs systems at Stocking Island and Highborne Cay have comparable histories. The microbial buildups are relatively recent additions to these reefs, with growth initiating 1,500–1,000 years ago (Macintyre et al., 1996; Andres et al., 2009). The distribution of metazoans (corals and coralline algae) vs. microbial components in the reefs is controlled by intensity and frequency of sediment stress, sand abrasion, and burial of reef biota (Steneck et al., 1998). Although the metazoans can stand some sediment stress, they cannot cope with extended periods of burial (Steneck et al., 1998). In contrast, cyanobacterial mats are largely unaffected by burial (Kromkamp et al., 2007; Perkins et al., 2007). Increasing sediment stress in the back reef lagoon of a coralline algae

ridge led to the demise of metazoans and prolific growth of stromatolites. The study of these modern analogs provides a process-oriented understanding of microbial reef development in time and space, which can be applied to the rock record (Andres et al., 2009).

## Summary

Stromatolites form an unusual and special type of reef. Unlike modern coral reefs, stromatolites are formed by microorganisms. These microorganisms trap and bind sand grains together and/or precipitate calcium carbonate to form laminated mounds of limestone. The layered internal structure of these reefs is a characteristic feature and the name “stromatolite” in Greek means “layered rock.”

Stromatolites dominated the planet for 80% of Earth history, forming massive reef complexes comparable to any built by corals or other frame-building organisms. The golden age of stromatolite growth was 2.5–1 billion years ago, during Early and Middle Proterozoic. Suffering a major decline with the appearance of eukaryotic plants and animals in the Late Proterozoic, stromatolites were confined to harsh environments lacking eukaryotes for much of the Phanerozoic.

Living stromatolites were unknown until the 1960s when they were discovered in Shark Bay, a hypersaline lagoon in Western Australia. They have since been found in numerous modern environments including saline, fresh water, and brackish settings. The only known examples of stromatolites forming in open marine environments similar to those of Precambrian platforms are on the margins of Exuma Sound, Bahamas. Exuma stromatolites are ideal model systems for studies of stromatolite morphogenesis. Lamination in these stromatolites results from a cycling of prokaryotic surface communities, with each layer in the subsurface “fossil” part of the stromatolite representing a former surface mat. Lithification of surface mats is syndepositional, and microbially induced. Exuma stromatolites are less than 1,500 years old; they thrive in locations where sediment stress restricts the growth of coral, macroalgae, and other reef-building eukaryotes. Studies of living stromatolites provide models for biogeochemical cycling, population dynamics, and mineral formation in the three billion year old microbial reef ecosystem.

## SUBMARINE GROUNDWATER DISCHARGE

Thomas Stieglitz

School of Engineering & Physical Sciences, James Cook University, Townsville, QLD, Australia

### Synonyms

Groundwater inflow; Groundwater seepage; Submarine springs

### Definition

Submarine groundwater discharge (SGD) is the direct discharge of groundwater across the sediment–water interface into estuaries, bays, and the ocean. SGD occurs “wherever an aquifer is hydraulically connected with the sea through permeable sediments” (Johannes, 1980). In addition to fresh, terrestrially derived groundwater discharge, SGD also includes the recirculation of seawater through seafloor sediments (Burnett et al., 2006).

On some coastlines, SGD is an important natural source of nutrients for coral reefs (Johannes, 1980; Paytan et al., 2006) and other coastal ecosystems. In coastal regions, with high anthropogenic nutrient loadings in groundwater, even a small net flux of submarine groundwater can deliver a comparatively large flux of nutrients to the sea (Burnett et al., 2006).

Terrestrially derived SGD can enter the ocean as slow seepage, discharging from sedimentary aquifers, and more rapidly from springs, rock fractures, or karst galleries. Generally, terrestrially derived SGD is confined to the nearshore zone, usually to waters less than 10 m deep, but some evidence exists for further offshore groundwater discharge, e.g., from “Wonky Holes” in the Great Barrier Reef (Stieglitz, 2005). Globally, the total discharge of fresh groundwater to the ocean is estimated at less than 10% of the surface input from rivers into the ocean (Gallardo and Marui, 2006).

SGD fluxes can be measured either directly with seepage meters (vented benthic chambers), or indirectly by their footprint on the physicochemical characteristics of the overlying water column, e.g., by temperature or salinity depth profiles, or by natural and introduced tracers (Burnett et al., 2006). Natural radioactive tracers such as radon and radium isotopes are enriched in groundwater, and are used to investigate larger-scale water exchange. In addition, hydrological methods such as water-balance approaches and numerical modeling are commonly applied to evaluate catchment-scale estimates of SGD.

## SUBMARINE LITHIFICATION

Ian G. Macintyre

Smithsonian Institution National Museum of Natural History, Washington, WA, USA

### Synonyms

Submarine Cementation

### Definition

Submarine lithification is a process by which coral-reef structures and associated sediments are lithified in their marine setting by the precipitation of submarine cements.

### Introduction

Little was known about this process of submarine lithification in modern coral reefs until the 1960s when first reports of submarine lithification were published from reefs off Barbados (Macintyre, 1967; Macintyre et al., 1968) and off Bermuda (Ginsburg et al., 1967). This was shortly followed by the 1969 Bermuda Conference on Carbonate Cements that brought together a major gathering of carbonate geologists to describe a variety of carbonate cements from both modern and fossil deposits with a focus on submarine lithification in modern coral reefs (Bricker et al., 1969). Subsequently, the phenomenon was more widely documented, notably in the reefs off Jamaica (Land and Goreau, 1970; Land and Moore, 1980), Bermuda (Ginsburg et al., 1971a, 1971b; Shinn, 1971; Ginsburg and Schroeder, 1973; Schroeder, 1972a, b; Schroeder and Zankl, 1974; Focke and Gebelein, 1978), the Red Sea (Friedman et al., 1974; Gvirtzman and Friedman, 1977; Brachert and Dullo, 1991), Belize (James et al., 1976; Shinn et al., 1982; Macintyre, 1984), the Caribbean coast of Panama

(Macintyre and Glynn, 1976; Macintyre, 1977, 1983), the Great Barrier Reef (Marshall and Davies, 1981; Marshall, 1983, 1986), Antigua (Macintyre et al., 1985), Florida (Lighty, 1985), and the Bahamas (Macintyre et al., 1996).

### Environmental conditions that promote submarine lithification

Two environmental conditions that appear to affect the degree of submarine lithification in coral reefs are (a) the period of time that a reef surface is exposed, which can be as much as 1,000–2,000 years for extensive lithification (Macintyre et al., 1968; Macintyre and Glynn, 1976; Macintyre, 1984), and (b) the amount of wave energy expended on a section of the reef. That is why reef zones having slow accumulation rates or subjected to high wave energy are extensively lithified, as is the case in the slowly accreting deeper fore-reef slopes of Belize (James and Ginsburg, 1979), Jamaica (Land and Moore, 1980), and the Red Sea (Brachert and Dullo, 1991) and in the wave-exposed seaward margins of the Great Barrier Reef (Marshall, 1986) and the algal reefs on the outer edge of the Bermuda platform (Shinn, 1971; Ginsburg et al. 1971a; Ginsburg and Schroeder, 1973). From a detailed study of submarine lithification in a fringing reef off Panama, Macintyre (1977) concluded that lithification is controlled by “the length of time that a section of the reef is exposed to near-surface conditions suitable for the precipitation of submarine cements” (p. 514).

Despite the assumed influence of wave energy, extensive submarine lithification can occur even in quiet lagoonal settings, as illustrated by the lithification found on the long-exposed ceiling of a submarine cave in the Belize lagoon (Macintyre, 1984) and exposed the areas of the Great Barrier Reef patch reefs such as One Tree Reef and Myrmidon Reef (Marshall, 1985, 1986). Although not yet lithified, micritic Mg-calcite has also been found precipitating in Belizean and Panamanian lagoonal sediments (Macintyre and Aronson, 2006).

### Composition of submarine cements

The cement found in modern coral reefs consists mainly of micritic Mg-calcite, along with minor amounts of aragonite (Macintyre and Marshall, 1988), although aragonite is more abundant in deeper outer slopes of reefs where large spectacular fans of “botryoidal aragonite” have been reported in Belize (Ginsburg and James, 1976, p. 431; James and Ginsburg, 1979, p. 117) and the Red Sea (Brachert and Dullo, 1991, p. 359).

The Mg-calcite cements characteristically consist of 14–19 mol%  $\text{MgCO}_3$ , ranging from 15 to 17% for Bermuda (Ginsburg and Schroeder, 1973), 18.5% for Jamaica (Land and Goreau, 1970), 16.6–18.8% for Panama (Macintyre, 1977), 14.5–16.3% for Belize (Macintyre, 1984), and 15.1–18.5% for Antigua (Macintyre et al., 1985). The strontium values of the aragonite cements are also fairly consistent: 8,120–8,460 ppm (Ginsburg and

James, 1976) and  $6,900 \pm 800$  ppm (Macintyre, 1984) for Belize;  $9,500 \pm 600$  ppm for Panama (Macintyre, 1977); 10,500 ppm for Jamaica (Land and Moore, 1980); and  $7,377 \pm 783$  to  $7,549 \pm 973$  ppm for Antigua (Macintyre et al., 1985).

Stable isotope values for Mg-calcite are consistent as well:  $+3.0\% \pm 1.0$   $\delta^{13}\text{C}$  and  $-0.5\% \pm 1.0$   $\delta^{18}\text{O}$  for Jamaica (Land and Goreau, 1970),  $+3.0$  to  $3.8\%$   $\delta^{13}\text{C}$  and  $0.0$  to  $+0.5\%$   $\delta^{18}\text{O}$  for dense Mg calcite from Belize, and  $+3.1$  to  $+3.5\%$   $\delta^{13}\text{C}$  and  $-1.1$  to  $-0.3\%$   $\delta^{18}\text{O}$  for Belizean microsugrosic Mg-calcite (Macintyre, 1984). Aragonite cements from the deep fore reef of Belize have yielded values of  $+3.3$  to  $+4.3\%$   $\delta^{13}\text{C}$  and  $+0.4$  to  $1.1\%$   $\delta^{18}\text{O}$  (James and Ginsburg, 1979).

### Textural characteristics of lithified reef frameworks

Lithified reef frameworks occur in two predominant forms, classified as micritic crusts and pavement limestones on the basis of their textures.

#### Lithified micritic crusts

The most common lithified reef texture consists of micritic Mg-calcite and varying amounts of sediment grains forming a crust on the upper surfaces of the coral framework (Figure 1). Crusts can be as much as 5 cm thick and cover any biota present on the surface, such as crustose coralline algae, bryozoans, foraminifera, serpulids, vermetids, and sabellarian tubes (Macintyre, 1977). In addition micritic Mg-calcite free of sediment grains penetrates up to 2 cm into coral skeletal cavities (Macintyre, 1977).

Petrographic studies reveal several distinct zones within the crust (Figure 1): sediment-rich micrite at the outer edge, grading into dense micrite, then a (20–60  $\mu\text{m}$ ) peloidal filling consisting of dense anhedral microcrystalline centers ( $>4$   $\mu\text{m}$ ) with microcrystalline (4–30  $\mu\text{m}$ ) well-developed dentate rims (Macintyre, 1985), and finally a porous submicrosugrosic ( $>4$   $\mu\text{m}$ ) Mg-calcite. At this inner limit, the coral skeletal sclerodermites have syntaxial overgrowths of acicular aragonite (Figure 1). This aragonite predates the Mg-calcite and rarely occurs in the same skeletal cavities (Macintyre, 1977).

Many of the thicker lithified crusts show distinct laminations described as “concentric laminations” (Land and Goreau, 1970, p. 406) and considered to be bedding surfaces. Some crusts contain inclined and overlapping bands (Figure 2), thought to indicate a “change in the slope of the accreting surface” (Macintyre, 1977, p. 507). Similar banding, described as “laminated mudstone in the form of irregular to superimposed domes” (James and Ginsburg, 1979, p. 135) has been found in the extensive lithified deposits of the deep fore reef off Belize, while “laminated micritic crusts” have been documented in the deep fore reef of the Red Sea (Brachert and Dullo, 1991, p. 361). Similar laminated crusts are also present in most major reef facies of One Tree Reef in the Great Barrier reef (Marshall, 1983).

(e) Submicrocrystalline Mg-calcite at the innermost limit of Mg-calcite precipitation (Macintyre, 1977).

### Pavement limestones

The densest type of lithified reef structure occurs in areas where reef accumulation has experienced a hiatus and wave action is heavy, usually in the shallow fore reef or the outer edge of the reef flat, as found in Samoa (Carey, 1931), Enewetak (Ladd, 1973; Henny et al., 1974; Tracey and Ladd, 1974), Jamaica (Goreau, 1959), Belize (James et al., 1976; Rutzler and Macintyre, 1982), Panama (Macintyre, 1977), and the Great Barrier Reef (Marshall and Davies, 1981; Marshall, 1983). The sea floor may be extensively lithified even in parts of the deep fore reef where slopes are too steep for active reef accumulation, as in the Eastern Caribbean (Macintyre, 1972), Belize (James and Ginsburg, 1979), Jamaica (Land and Moore, 1980), and the Red Sea (Brachert and Dullo, 1991).

Typically, these heavily lithified areas of the sea floor have been exposed to long periods of boring, subsequent sediment filling, and micritic precipitation, with the result that the original skeletal framework has in many instances been entirely replaced by sediment-rich micritic Mg-calcite (Figure 3). This pattern is well documented in the reefs of Bermuda (Ginsburg and Schroeder, 1973; Schroeder and Zankl, 1974), Belize (James et al., 1976; James and Ginsburg, 1979), Panama (Macintyre, 1977, 1983), Jamaica (Land and Moore, 1980), and the Red Sea (Brachert and Dullo, 1991).

Another common feature of pavement limestones is a buried irregular eroded surface with an amorphous medium brown to black coating (Figure 3). These "hiatal corrosion surfaces" (Macintyre and Marshall, 1988,

**Submarine Lithification, Figure 2** Inclined overlapping band in a micritic Mg-calcite crust on a Gelata reef, Panama coral (Macintyre, 1977).

p. 267) are said to resemble stylolitic structures in their irregularity, although “their lower surface is the only one truncating skeletal grains” (Macintyre, 1977, p. 510). Similar hiatal surfaces have been reported as “organic layers” in hard grounds in the Persian Gulf (Shinn, 1969, p. 124) and as dark coatings of iron and manganese oxides from the deep fore reef of Belize (James and Ginsburg, 1979) and Jamaica, where they are thought to represent “local inconformities or times of slow or bypassed sedimentation” (Land and Moore, 1980, p. 359).

### Origin of submarine lithification in coral reefs

The causes of submarine lithification in coral reefs are still not fully understood. Observations and experiments suggest that various organisms may play either a direct or indirect role in the precipitation of submarine cements.

Because well-lithified substrates occur in areas of heavy wave action, it has also been suggested that the pumping

**Submarine Lithification, Figure 3** Densely lithified pavement limestone showing multicyclic boring and infilling by sediment-rich micritic Mg-calcite that has almost totally replaced the original skeletal framework. Remnants of *Agaricia agaricites* (Ag), *Millepora complanata* (MI), and crustose coralline algae (CA) in a micritic Mg-calcite sediment-rich matrix includes *Halimeda* (Ha) and mollusc (M) grains. Note the stylolitic-like (Sty) dark hiatal corrosion surfaces (Macintyre, 1977).

action of waves (Mathews, 1974), as well as a reduction of  $\text{CO}_2$  due to pressure changes associated with heavy wave activity (Ginsburg et al., 1971b), may promote carbonate precipitation. The effect of wave-pumping activity may also be supplemented by supersaturation and low rates of accumulation (Focke and Gebelein, 1978).

Nonetheless, biological factors may play a more important role, as suggested by  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  enrichment in micritic crusts caused by organic-induced fractionation when crusts were formed (Land and Goreau, 1970). Further evidence of this role comes from the fatty acids present in micritic crusts, which are similar to the straight-chain 16-carbon acid formed by bacterial activity. "Micritic tubes" documented on the surface of some micritic crusts and thought to represent "filamentous algae, bacteria or fungi" (Brachert and Dullo, 1991, p. 357) provide additional support for a biological inducement in the precipitation of micrite. However, bacteria and fungi may have a more indirect effect, as indicated by laboratory experiments (Towe and Malone, 1970) in which the precipitation of both aragonite and Mg-calcite was observed following the release of ammonium carbonate in seawater (Figure 4). It was concluded "because ammonium carbonate can be a natural by-product of biological activity this suggests a mechanism by which such mineral phases might occur locally in marine conditions" (Towe and Malone, 1970, p. 348). This hypothesis was strongly supported by observations of major deposits of Mg-calcite coating serpulid tubes on the ceiling of a cave in the lagoon of the Belizean Barrier reef (Macintyre, 1984). Submarine lithification obviously proceeded without the assistance of wave activity in this extremely protected setting. The buildup of ammonium by-products resulting in the precipitation of

calcium carbonate here may have been due to the decay of significant amounts of fecal deposition in the cave related to the high concentrations of fish over the cave opening.

This then calls into question the actual role of wave activity in the lithification of reef substrate, especially since submarine lithification occurs by and large in shallow subsurface settings where skeletal debris is easily trapped pumped into the substrate (Ginsburg et al., 1971b; Macintyre and Glynn, 1976; Macintyre, 1977). Undoubtedly, organic debris would also be pumped by waves into the substrate, and this debris would slowly decay to yield ammonium carbonate and lead to the precipitation of the characteristic micritic crusts containing sediment grains (Macintyre and Marshall, 1988).

The decay of organic tissue has also been cited as a factor in the lithification of Red Sea reefs, along with the removal of carbon dioxide by the "photosynthesis and respiration of the biomass of the reef" (Friedman et al., 1974, p. 816). Some laboratory experiments support the idea that high pH levels can result from "photosynthetic activity in seawater trapped in corals and algal meadows" (Epstein and Friedman, 1982, p. 165).

Other possible entities contributing to the formation of carbonate cements are sulfate-reducing bacteria (Pigott and Land, 1986). However, their role is likely to be very limited because well-lithified reef deposits show little evidence of the iron monosulfides or pyrite expected from the release of hydrogen sulfide associated with such bacterial activity.

## Conclusions

Submarine lithification is a widespread phenomenon that binds the framework of coral reefs with cement produced in a marine setting. The resulting lithified structure consists mainly of micritic Mg-calcite in the form of crusts or heavily multibored and multicemented pavement limestones. Aragonite is a minor component of lithified structures in shallow waters but becomes more dominant in the deeper reef slopes. The mole percent  $\text{MgCO}_3$  of this Mg-calcite ranges from 14 to 19%, and the strontium content of the aragonite ranges from 6,900 to 10,500 ppm. The factors that induce submarine lithification are still not entirely clear. However, the decay of organic material does appear to play an important role in yielding an ammonium carbonate by-product that results in the precipitation of carbonate cements.

## Definition

Submerged reefs are reefs formed during periods of lower sea level, which currently have little or no modern upward coral framework accretion. These reefs are found in water depths ranging from 25 to 2,000 m depending on their tectonic setting, but most commonly between 40 and 120 m on passive continental margins. They are thought to have drowned as a result of inimical environmental conditions associated with sea level rise during the last deglaciation.

## Introduction

Glacial and interglacial cycles have driven sea level oscillations over the last 500 ka, with extremes of at least –120 to +5 m relative to the present day sea level. Since the last glacial maximum of 19–20 ka, sea level has risen approximately 120 m (see Chapter *Postglacial Transgression*). Within this time period, episodes of dramatically faster sea level rise punctuated an otherwise fairly steady transgression (see Chapter *Meltwater Pulses*). The impacts of this extreme environmental change on reefs were varied and often detrimental to coral growth, including rapidly

increased depth and re-suspension of sediments during flooding of the shelves (see Chapter *Sea Level Change and Its Effect on Reef Growth*). These inimical conditions acted to slow the rate of reef accretion while sea level rise put them outside of the zone of optimal growth. Today, submerged reefs may have live coral cover in some cases, yet they are not believed to be making significant vertical progress towards the sea surface (e.g., Harris et al., 2004).

Submerged reefs have intrigued researchers since their earliest detection at the turn of the twentieth century (e.g., “submerged barrier reefs” of Barbados, Jukes-Browne and Harrison, 1891). Scientific interest accelerated in the late 1960s when these submerged reefs began to be readily interpreted as products of lower sea levels (e.g., Macintyre, 1967). It was not long before their worth as archives of past environments and climates was recognized, and with their associated corals, came to be firmly established as reliable records of palaeoenvironmental changes (e.g., Montaggioni and Macintyre, 1991) and rapid sea level fluctuations (Fairbanks, 1989). More recent studies are beginning to reveal the subtle complexities of climate and environmental change that have shaped the formation of each of these relict reefs (for a review, see Montaggioni, 2005).

## Tectonic setting and geology

Submerged reefs can be divided as follows into three broad categories based on their geologic and tectonic setting: (1) reefs lying on stable continental margins, shelves, or platforms (e.g., The Seychelles, in the Indian Ocean, are composed of granitic continental crust and not the typical volcanic material of mid-plate oceanic islands, such as Hawaii or Tahiti.) with no significant vertical movement; (2) reefs lying on active tectonic margins with significant vertical movement, and (3) reefs surrounding subsiding oceanic islands.

Well-documented submerged reefs of passive continental margins include those of southern Florida, Australia's Great Barrier Reef, the Laccadive Islands, and other reefs off India's western margin. These submerged features display a wide range of morphologies, including terraces, barrier reefs, platforms and shoals, pinnacles and patch reefs, and reef-related features such as palaeo-lagoons (e.g., Figure 1). A commonality among many passive margin features is their great extent and continuity. India's continental margin contains 1,300 km of intermittent submerged reefs (Vora et al., 1996), and terraces on the outer shelf of the Great Barrier Reef have been observed to extend for hundreds of kilometers along the shelf edge (Hopley et al., 2007 pp. 285–296; Beaman et al., 2008). They generally range in depth from 25 to 120 m.

Submerged barrier reefs and terraces are also commonly found on slowly subsiding mid-plate oceanic islands, such as Tahiti, Hawaii, Marquesas, and Mayotte. As is the case on the islands of Hawaii, submerged reefs can be found at extreme depths as well, ranging from several hundred to nearly 1,500 m below sea level, depending on the rates of subsidence (Ludwig et al., 1991; Webster

**Submerged Reefs, Figure 1** Bathymetric map of the shelf edge near Noggin Pass, Great Barrier Reef, surveyed onboard the RV *Southern Surveyor* (SS07/2007). Area is gridded at 5 m<sup>2</sup> resolution and displayed using IVS3D Fledermaus. Images reveal extensive submerged terraces, pinnacles, and platform features along the shelf edge, as well as the existence of a possible palaeo channel. White represents no data. Note that scale varies with perspective view.

et al., 2004) (see Chapter *Hawaiian Emperor Volcanic Chain and Coral Reef History*). This is possible as much older Pleistocene reefs were never sub-aerially exposed during sea level regression of the last glacial period, and have been preserved in the rock record. As islands subsided and sea levels retreated at similar rates, reefs remained underwater and continued to grow. Subsequent island subsidence and sea level rise during the last deglaciation are responsible for the great depths at which these reefs are found today.

Zones of active tectonism are less commonly associated with submerged reefs, yet these relationships do occur. Barbados is one of the best known examples of slowly uplifted submerged reefs. The island is positioned on an accretionary prism with vertical movement of  $\sim 34 \text{ cm kyr}^{-1}$  (Fairbanks, 1989); however, the rate of deglacial sea level rise outpaced uplift and accretion, and these reefs were left submerged. With much time and continued uplift, they will theoretically break the sea surface and become sub-aerially exposed in the distant future (see Chapter *Emergent Reefs* and *Huon Peninsula, P.N.G.* as an example). An alternative scenario includes the rapidly subsiding reefs found in the Huon Gulf, Papua New Guinea. The combined effects of sea level rise and rapid subsidence have submerged these reefs to depths of  $\sim 2,000 \text{ m}$  (Webster et al., 2009).

### Submerged reef morphology

Morphological variations observed in submerged reefs are comparable to modern shallow reefs. High-resolution

bathymetry datasets, such as that seen in Figure 1, are the most accessible method of analyzing sea floor topography and any reef features. For instance, steep-sided pinnacle structures are thought to be submerged patch reefs (see Chapter *Patch Reefs: Lidar Morphometric Analysis*), and raised ridges or an extensive row of partially joined pinnacles are thought to be submerged barrier reefs (e.g., Figure 2) (see Chapter *Barrier Reef (Ribbon Reef)*). Recent work classifying reef features in a quantitative manner will make the task of standardizing terminology more attainable (Zieger et al., 2009).

Submerged reef morphology is thought to be influenced by palaeo-sea level variations (e.g., Brock et al., 2008) but also by the complex history of multiple phases of growth and erosion through many glacial and interglacial cycles (e.g., Beaman, Webster et al., 2008). The buried boundaries between depositional phases can be detected and mapped using seismic emissions which penetrate the substrate and show variations in reflectivity between lithologies (see Chapter *Seismic Reflection*). This type of information can provide insight into the morphology of the sea floor and basement prior to reef initiation and how its shape has influenced subsequent reef development.

### Geological significance

Submerged reefs carry great significance as recorders of past geological and environmental or climatic events. The unique physical properties of fossil corals and their ecological tolerances have made them useful to many

**Submerged Reefs, Figure 2** Submerged reef structures on the shelf edge near Noggin Pass, Great Barrier Reef. Identified features include parallel barrier reefs comprised of a raised ridge and pinnacles, a lagoon containing patch reefs, and seaward terraces. Gridding and display as per Figure 1, however, note 3× vertical exaggeration. Scale varies with perspective view.

studies, for example, as proxies for oceanic conditions (see Swart and Grottoli, 2002 for a review of recent work). After death, their hard skeletons, comprised of calcium carbonate ( $\text{CaCO}_3$ ), are readily preserved in situ, and environmentally driven isotopic fractionation and trace element ratios within their skeletons can be calculated (see Chapter *Palaeoclimate from Corals*).

Often, modern corals are used for recent climate reconstruction (see Grottoli and Eakin, 2007 for a discussion of  $\delta^{18}\text{O}$  and  $\Delta^{14}\text{C}$  records), but fossil reefs can extend the known record of climatic variations, and in particular submerged fossil reefs, as they tend to offer more pristine material than those subjected to the diagenetic effects of meteoric water and sub-aerial exposure. One very powerful property of corals is their capacity to be reliably dated using both radiocarbon and uranium series methods (see Chapter *Radiocarbon ( $^{14}\text{C}$ ): Dating and Corals* and *Uranium Series Dating*). When used in tandem with climate proxy records, much older high-resolution (on the order of seasonally or yearly) historical climate data can be obtained from these deeper submerged reefs. This method is particularly insightful when identifying oceanic conditions prior to reef death, as it may be compared to the prevailing conditions on today's modern reefs.

Reefs are also particularly useful for reconstructing past changes in relative sea levels. It is well understood that many corals (Done, 1982) and associated coralline algae (Adey, 1986) have narrow depth, energy, and water quality tolerances (see Chapter *Corals: Environmental*

*Controls on Growth and Fossil Coralline Algae*), making them excellent recorders of historical oceanographic conditions, sea level fluctuations, and tectonic movements. Scientific drilling has been the preferred method of investigation into submerged reefs for sea level reconstruction, as current technology makes it a relatively noninvasive endeavor in sensitive and protected ecosystems (see Chapter *Reef Drilling*). Drilling can often reveal the entire postglacial sequence of coral growth and subsequent death. Significant changes observed in these coral reef communities through time can be interpreted in the context of environmental and sea level fluctuations, in some cases revealing catastrophic events, such as the meltwater pulses (1A and 1B) seen in the Barbados reef record (Bard, 1990). However, local tectonics and isostatic response can produce conflicting sea level signatures across the globe. The Integrated Ocean Drilling Program (IODP) has recently completed large-scale drilling operations of submerged reefs on Tahiti (IODP Expedition 310 “Tahiti Sea-Level” in 2005, see Expedition 310 Scientists, 2007) and the Great Barrier Reef (IODP Expedition 325 “Great Barrier Reef Environmental Changes” in 2010, see Webster et al., 2009). As more reefs are investigated, further reconciliation of sea level curves across wide geographic areas can be achieved. For a comprehensive review of Indo-Pacific drilling and interpretation of reef facies, see Montaggioni (2005).

Large-scale morphological features detected with remote sensing technologies also provide geological and

sea level information. Parallel sequences of submerged terraces have been interpreted as reef backstepping due to sea level rise (see Chapter *Back-Stepping*). As the seas transgress inland, reefs re-establish themselves on newly submerged surfaces. Geophysics can also be used to detect large-scale features, such as the original surface upon which the reefs initiated. These surfaces are buried today, but subsurface seismic reflections can indicate their locations. By establishing the depth of the original substrate, reef thickness can be calculated, and with enough coverage, the general morphology of the older sea floor and basement substrate can be interpolated (see Chapter *Holocene Reefs – Thickness and Characteristics*).

However, caution must be taken when using corals to reconstruct global sea level fluctuations, as tectonic events can effectively raise or lower relative sea level. With this understanding and knowledge of global sea levels from more stable regions, submerged reefs can be useful for calculating the timing and amplitude of local subsidence or uplift. For example, the Hawaiian Islands' long history of tectono-volcanism can be observed in its coral reefs. Corals have been collected from great depths and dated to determine the rates of subsidence on the islands as well as to investigate the oceanographic properties of the larger Hawaiian-Emperor chain (see Grigg, 1997 for a review).

### Modern significance

The extreme depth of many submerged reefs has hindered modern ecological investigations because the costs and technology required to access such areas are often excessive. As a result, the understanding of mesophotic coral reefs (30 to 150 m water depth) has been slow to develop. While hermatypic corals generally thrive in shallow water environments (<20 m), light-dependent communities of corals, algae, and sponges have been documented at depths >100 m in the Caribbean, Hawaii, and Central Pacific (see Lesser et al., 2009 for a review on modern mesophotic reefs). Australia's living submerged reefs in the Gulf of Carpentaria (Harris et al., 2004) and the Great Barrier Reef (e.g., Webster et al., 2008) are presently the subjects of similar research. It is thought that these ecosystems may provide refuge habitats for reef biota during times of extreme environmental stress in the shallower regions (see Bongaerts et al., 2010 for a review). This retreat to deeper waters may have been a strategy corals have invoked during past sea-surface warming events. Shallow reefs may have been re-seeded by deeper refuge reefs post disturbance, staving off localized extinction events and adding a significant degree of resilience to these ecosystems. A lack of understanding and information about these deeper reef habitats has also precluded any significant organized management. These regions often lie outside restricted fishing and recreation areas, with governing bodies unaware of the existence of these habitats.

### Conclusions

The study of submerged reefs is invaluable to our knowledge of palaeoclimate, sea-level, and oceanographic processes. With an understanding of ancient reef response to climate disturbances, modern reefs subjected to today's stresses can be better managed. Rates of reef initiation and drowning can be calculated, and when coupled with palaeoclimate data, a more comprehensive understanding of controls on reef growth, development, death, and recovery can be attained (see Chapter *Historical Ecology of Coral Reefs*). Additionally, a number of these submerged reefs may provide modern reef habitats presently in need of management. The value of submerged and fossil reefs as proxies for modern reef response to global climate change is unparalleled, and as interest in historical reef records intensifies and technology improves, a more comprehensive understanding of submerged reefs will unfold.

## SUBSIDENCE HYPOTHESIS OF REEF DEVELOPMENT

Colin D. Woodroffe

University of Wollongong, Wollongong, NSW, Australia

### Definition

The subsidence hypothesis of coral reef development was proposed by Charles Darwin and was formulated during his voyage on the *Beagle*. It envisaged that fringing reefs, barrier reefs, and atolls represent successive stages in an evolutionary sequence.

### Introduction

In a remarkable deduction, Charles Darwin proposed that different types of coral reef observed in mid ocean came about through the subsidence of underlying volcanic foundations. He envisaged that fringing reefs, barrier reefs, and atolls represented different stages as a result of vertical growth of reefs on subsiding basements. Subsequent drilling has provided support for this idea, which can be integrated into plate tectonic theory, and can also accommodate many factors associated with changes in sea level.

### Darwin's insight into atoll formation

At the time of Darwin's voyage on the *Beagle*, it was unclear how atolls had formed. A widely accepted view was that advanced by Charles Lyell who had proposed, in his *Principles of Geology*, which reached Darwin while on the voyage, that the annular rim of an atoll represented a coral veneer over the rim of a volcano (Lyell, 1832). Darwin formulated his "subsidence theory for reef development" shortly after leaving the coast of South America, where he saw evidence of marine deposits uplifted well above sea level and the aftermath of an earthquake, and before he encountered the numerous coral reefs of the Pacific.

Darwin proposed an alternative view: "namely the prolonged subsidence of the foundations on which the atolls were primarily based, together with the upward growth of the reef-constructing corals. On this view every difficulty vanishes: ...fringing reefs are thus converted into barrier-reefs; and barrier-reefs, when encircling islands are thus converted into atolls, the instant the last pinnacle of land sinks beneath the surface of the ocean" (Darwin, 1842, p. 109). As his sketch showed (Figure 1), these "three great classes" of reefs were stages in an evolutionary sequence, driven by gradual subsidence of the volcanic island around which the reef had initially formed.

Darwin had the opportunity to visit Tahiti in November 1835, from the slopes of which he looked over to the spectacular barrier reef surrounding neighboring Moorea. He refined his idea after leaving the Society Islands on his voyage to New Zealand (Stoddart, 1962). After the *Beagle* had visited Australia, it called at the Cocos (Keeling) Islands in April 1836. As this was the only coral atoll on which Darwin landed, he was keen to verify his hypotheses.

**Subsidence Hypothesis of Reef Development, Figure 1** Details of Darwin's original woodcut (1842) illustrating his subsidence hypothesis. In the upper diagram the original volcanic island is shown with a *fringing-reef* A-B. A section of reef and island after subsidence is given by *dotted lines*, which show an encircling *barrier-reef* with A' the outer edge of the reef, B' the shore of the encircled island, and C the lagoon channel between the reef and island's shore. In the lower diagram the newly formed barrier reef is represented by *unbroken lines*. As the island continues subsiding the coral reef will continue growing up on its own foundation, and after the sea covers the highest volcanic pinnacle a "perfect atoll" is formed with A'' representing the outer edge and C' the lagoon of the newly formed atoll (from McLean and Woodroffe, 1994, © Cambridge University Press, reproduced with permission).

His attention was drawn to erosion of the shoreline, and he regarded the undercutting of coconut trees "tolerably conclusive evidence" in support of his ideas.

On return to England, his geological observations on coral reefs were amongst the first of his results that he wrote up. He presented a paper to the Geological Society on May 31, 1837 (Darwin, 1838), and then produced a book on his observations on coral reefs, integrated with evidence extracted from charts of reefs he had not visited (Darwin, 1842). In this book, Darwin produced a map of the location of the reef types, atolls predominantly occurring in mid ocean, whereas fringing reefs were found around the margin of the Pacific in areas we now know to be plate-margin settings.

### Alternative theories

Darwin's subsidence hypothesis for reef development has played an important part in the historical development of reef formation ideas (Steers and Stoddart, 1977). A number of alternative hypotheses were proposed. For example, John Murray, influenced by his observations of deep-sea sediments during the *Challenger* expedition, believed that atoll lagoons formed through solution of carbonate, and that atoll reefs prograded around their margin

(Murray, 1880). Murray sponsored Guppy to visit the Cocos (Keeling) Islands, and in his detailed descriptions of the reef islands there, Guppy inferred evidence supporting progradation (Guppy, 1889).

Considerable support was expressed for Darwin's subsidence ideas, in particular, by Dana (1885), a member of the US Exploring Expedition to the Pacific Ocean, 1838–1842. He read about Darwin's ideas in a Sydney newspaper, and he became a fervent supporter of subsidence. Dana observed that shorelines of volcanic islands behind barrier reefs comprised a series of embayments implying that valleys had been submerged during subsidence. Later William Morris Davis, who had made such a major impact on geomorphology through his ideas of a geographical cycle, undertook an extensive review of the "coral reef problem," and possible explanations of how atolls had formed. Davis extended Dana's argument that embayments in volcanic shorelines represented drowned valleys and emphasized that there was insufficient detritus trapped in lagoons for erosion of the hillslopes to have occurred after the reefs formed. He expressed the view that Darwin's subsidence hypothesis was the most probable but that the only contender was that proposed by Daly (Davis, 1928).

Reginald Daly, who replaced Davis at Harvard, placed particular emphasis on changes in sea level that he realized had occurred during Quaternary ice ages. During glacial periods, when sea level was 100 m or more lower than present, Daly believed that atoll rims were entirely truncated, and modern rims had accreted vertically during the postglacial (Daly, 1915, 1925, 1934). A perceived regularity to the depths of lagoons was inferred to support this “glacial-control” view, which was strongly advocated by Wiens (1959, 1962). A glacially controlled subsidence hypothesis was advanced by Kuenen based on Indonesian reefs (Kuenen, 1933).

A number of studies came up with significantly different interpretations of reef formation. However, many of these were focused on reefs in tectonically uplifted areas, or continental margins, such as the Great Barrier Reef. Darwin’s subsidence hypothesis of reef development addresses oceanic reefs, and in particular, the formation of atolls, and the recognition that reefs from plate-margin settings deviate from this mode of evolution does not invalidate application of the subsidence model to oceanic reefs. Many of these anomalies were incorporated into subsequent editions of Darwin’s book “Coral Reefs”. Comprehensive reviews of these alternative ideas can be found in Cotton (1948), Hopley (1982), and Spencer et al. (2008).

One set of alternative hypotheses, that considered the form of modern reefs to be controlled by the older surfaces over which they had grown, deserves particular attention. Alexander Agassiz undertook a series of descriptive accounts of Pacific and Indian Ocean reefs (Agassiz, 1899, 1903). His observations were often superficial, interpreting reef blocks as outcrops of older underlying rocks, but he was convinced that modern reefs were a thin veneer over antecedent topography. Such ideas recur in the study of reefs; for example, Hoffmeister and Ladd (1944) proposed what they called the antecedent platform hypothesis. The significance of subaerial erosion and dissolution of emerged platforms exposed during glacial lowstands were emphasized by MacNeil (1954).

Shallow drilling of modern reef rims on atolls has frequently encountered an older reef limestone of Last Interglacial age, described below. Successive episodes of reef formation are separated with depth by a series of solutional unconformities. Exposure of these surfaces during glacial periods, when sea level was 100–120 m lower than present, and their karstification, form a major part of the antecedent karst hypothesis of Purdy (1974), which received much support from seismic profiling.

### Evidence from deep drilling

Darwin was aware that the strongest evidence to support his theory would come from drilling into the foundations of atolls, and he had written to Alexander Agassiz in 1881, “would that some doubly rich millionaire would take it into his head to have borings made in some of the Pacific and Indian atolls and bring back cores for slicing from 500–600 ft.” Such an attempt was made by the Royal

Society of London, together with Australian scientists on Funafuti (then part of the Ellice Islands, now Tuvalu). Between 1896 and 1898, expeditions to this atoll met with varying success. Under Sollas in the first year, coring reached 32 m, under Edgeworth David in the second year it reached 219 m, and under Finckh in the third year it finally reached 340 m (Spencer et al., 2008). At this depth, the substrate was dolomitic shallow-water carbonate; the underlying volcanic rock had not been encountered, but the recovery of shallow-water sediments at such a depth did provide some support for subsidence (McLean and Woodroffe, 1994).

However, it was postwar deep drilling on the Micronesian atolls of Bikini and Eniwetok, as part of atomic bomb testing, which encountered more than 1,000 m of limestones over a volcanic foundation that provided the strongest validation for the concept of gradual subsidence (Emery et al., 1954). Subsequent drilling on other atolls, such as Midway in the Hawaiian chain and Mururoa and Fangatafu in French Polynesia, provided further validation “with a certainty rarely obtained in geomorphology” (Guilcher, 1988, p. 70).

### Accommodating the subsidence hypothesis into plate tectonic theory

It has also been necessary to reconcile the idea of subsidence with the considerably enhanced understanding of the sea floor and plate tectonics. Atolls are frequently found in linear archipelagoes, and linear island chains are now understood to form as the ocean lithosphere moves over a “hot spot” (Scott and Rotondo, 1983). The Big Island of Hawaii is the best example of a young, volcanically active island. The successive high islands in the chain to the northwest of this island are progressively older. Subsidence can occur, both through isostatic adjustment of ocean crust to the mass of the volcanic island, the process that explains the rapid subsidence of the Big island, or through the gradual cooling and deepening of the plate as it migrates further from the mid-ocean spreading center (Figure 2). Thus, the islands in the Society Island chain, from Tahiti and Moorea to much smaller volcanic masses, such as Borobora and Huahine, represent this stage of barrier reef development. Atolls, such as those of the Tuamotu (though not in the same chain) are the ultimate stage, with the possibility that they may eventually become submerged as seamounts if the rate of vertical reef growth cannot keep pace with subsidence [as occurs beyond the latitudinal limit to reefs, a point called the Darwin Point (Grigg, 1982)].

### Sea-level fluctuations and the significance of karst erosion processes

Drilling through limestones that underlie atolls has revealed great thicknesses of shallow-water carbonates, confirming the continued, though interrupted, accumulation of limestone over the Cenozoic. However, during the Pleistocene, oscillations in sea level of 100 m or more

**Subsidence Hypothesis of Reef Development, Figure 2** Schematic examples of fringing reef, barrier reef, and atoll [based on the original sketches by Davis (1928)], and the relationship of such islands along a schematic linear island chain on the Pacific plate (after Scott and Rotondo, 1983). Linear island chains illustrate several of the stages; for example, the Big island of Hawaii represents an example of a volcanic island that is still active, and an incipient reef is forming on some shorelines. Oahu further along the chain has several former reef units, including elevated limestones of last interglacial age. A barrier reef is also represented by an almost atoll, where a volcanic island persists as a small outcrop of volcanic rock with a surrounding barrier reef, such as Aitutaki in the Cook Islands or Borabora in the Society Islands. There are numerous examples of atolls; some of the smaller islands in such archipelagos consist of a single island on a table reef. The lower diagram shows a schematic representation of how such islands might be distributed along an idealized chain, with plate motion from the spreading center (mid-ocean ridge) at the left, toward the ocean trench at the right.

have meant that there have been interruptions to the upward accretion of reef. It is necessary that there be accommodation space for sedimentation, and this is eliminated when the sea falls below the surface of the carbonate platform. Dating of sequences of the upper limestones has shown that these record successive highstands. The majority of reefs are underlain by a reef unit of Last Interglacial age (approximately 120,000 years BP, Thurber et al., 1965; Marshall and Jacobson, 1985; Woodroffe et al., 1991), which has been termed the Thurber discontinuity. This occurs at around 12 m below sea level on the Cocos (Keeling) Islands and around 15–20 m below sea level on many Pacific atolls. In several cases, this has been shown to be underlain by an older highstand (approximately 240,000 years BP, Szabo et al., 1985).

Exposure of the reef platform has meant an interruption in vertical accumulation of carbonate, but it is still the case that subsidence accounts for the larger thickness of limestones where there has been a greater rate of subsidence, and hence there has been a greater accommodation volume over time. However, it is less clear to what extent the platform has been denuded during these periods of exposure. The processes of karst erosion exert a major

control, and they act to lower the surface and have played a role in dissolution of atoll lagoons (Purdy and Winterer, 2001). Direct evidence in support of the transition from fringing reef to barrier reef and from barrier reef to atoll is also rare.

It is important to emphasize that the subsidence hypothesis is most appropriate for mid-ocean islands, whereas the largest barrier reefs such as the Great Barrier Reef and the Belize Barrier Reef are on continental shelves where Darwin's ideas are less likely to apply (Hopley, 1982). The role of dissolution of limestone on fringing reefs and barrier reefs is not adequately incorporated into the subsidence hypothesis (Purdy and Winterer, 2006). The significance of fluctuations in sea level was not realized when Darwin developed his ideas. It now seems clear that the transition from fringing reef to barrier reef is not as simple as portrayed in the schematic diagrams; indeed, there are many islands on which both fringing and barrier reefs occur around their margin. Furthermore, karst erosion processes have been extremely effective at producing barrier reef morphology, as on the makatea island, Mangaia in the Cook Islands, through solution of older reef units by percolation of rainwater across the underlying volcanic rock (Stoddart et al., 1985).

## Summary

Although the premise that uplift around the margin of an ocean might be balanced by subsidence beneath the ocean floor, which underpinned Darwin's hypothesis, is now seen to be simplistic and flawed, his remarkable deduction that such subsidence would give rise to three types of reefs, fringing reefs, barrier reefs, and atolls, has been broadly validated by stratigraphy and dating of cores through atolls. There are numerous exceptions to this sequence of development, particularly for those reefs on continental margins or that have experienced uplift. Nevertheless, gradual subsidence characterizes ocean lithosphere as it migrates from mid-ocean ridge (spreading center) to ocean trench. Although fluctuations in sea level have punctuated the development of atolls, with periodic exposure and karstification of the carbonate platform, gradual subsidence has persisted with successive veneers of reef limestone added during each highstand. There seems little doubt that this powerful hypothesis can be extended to explain the broad evolution of many mid-ocean atolls for which coring has not yet confirmed an underlying volcanic basement.

## SWATHE MAPPING

---

Robin J. Beaman  
 James Cook University, Cairns, Queensland, Australia

### Synonyms

Multibeam Mapping; Multibeam Sonar Mapping

### Definition

*Swathe mapping.* A technology used for the detailed 3D mapping of the seabed utilizing a vessel-mounted multibeam sonar that transmits a fan, or swathe, of acoustic energy across the ship track; then resolves multiple depth points across the swathe based upon the slant range and elevation angle of reflected echoes from the seafloor. Lidar is a similar technology to multibeam but using airborne laser bathymetry to swathe map shallow clear waters.

### Multibeam sonar

Singlebeam echo sounders have been applied routinely for many years to collect bathymetric or depth data from the world's oceans. This acoustic technique relies on a vessel-mounted transducer to generate a single acoustic pulse directed toward the seabed underneath the vessel. The echo sounder then calculates a depth measurement based on the travel time for the reflected seafloor echo to return to the receiver and speed of sound through water (Kunzig, 2000). During the 1970s, development began on multibeam sonar systems that use a multielement transducer array to transmit a fan, or swathe, of acoustic energy across the vessel's track. The swathe is narrow in the along-track direction, typically 1–2°, and wide in the across-track direction, generally 120° or more (Blacquire and van Woerde, 1998). The transmitted acoustic pulse frequency ranges from higher frequencies up to 450 kHz for mapping shallow coastal waters and the continental shelf, down to lower frequencies of 12 kHz for mapping the deep abyssal seafloor (Wille, 2005).

The multibeam receiver array measures the slant range and elevation angle of multiple seafloor echo returns across the swathe, and usually the echo strength of the returns which is called backscatter or amplitude. The multibeam sonar system also tracks the precise position of the vessel and motion data, such as gyro heading, heave, pitch, and roll, to calculate an accurate depth and position for the individual depth soundings. The number of depth measurements across the swathe varies between instruments but can be hundreds to thousands of soundings per second (Lekkerkerk, 2006). As long as the vessel is moving forward relative to the seabed, a multibeam swathe survey results in a dense “point cloud” of soundings that can be used to generate a 3D depth model, which accurately maps the underwater landscape (Figure 1). The resolution of seabed features that can be detected in such depth models can be sub-meter in size for shallow waters. However, in deeper waters, the resolution of observed features reduces to tens of meters due to the spreading properties of acoustic energy over longer distances and the lower frequencies used to ensonify the seafloor (Wille, 2005).

### Lidar

A similar seafloor mapping technique to multibeam sonar is the use of airborne laser bathymetry, or light detection and ranging (lidar), which use low-flying aircraft to scan pulsed laser beams across the seafloor and generate a swathe of depth soundings (Guenther, 2007). For example, the laser airborne depth sounder (LADS) uses a narrow infrared (1,064 nm) beam fired directly at the sea surface beneath the aircraft but does not penetrate the water, and thus reflects directly back to aircraft for calculating the aircraft's height above the water. A scanning mirror reflects a second green (532 nm) laser that tracks back and forth across the flight path in a grid pattern. The scanned green laser penetrates the water column to a limit of about 50–70 m (in clear water) that reflects off the seabed, if lying within this depth limit. The airborne receiver detects any reflected green laser signals and converts the returned signals into multiple depth points after subtracting the aircraft height value obtained from the infrared laser (Guenther, 2007).

Data density and acquisition rates vary between lidar instruments but typically collect about 1,000 depth soundings per second, with a swathe width of 200 m while flying at a height of about 500 m. At this height, the green laser beam footprint at the sea surface is about 2 m while the actual grid spacing can vary from 2 to 10 m apart. With aircraft speeds of about 150–175 km, lidar can deliver fast, high-resolution, shallow water surveying capabilities compared to vessel-mounted multibeam sonar systems (Guenther, 2007). The major disadvantage of lidar compared to multibeam is that laser signals are highly attenuated in turbid water and, therefore, lidar is ideally suited for surveying only in clear shallow waters. However, tropical coral reef areas provide additional navigational

**Swathe Mapping, Figure 1** Composite image showing the 3D effect of swathe mapping an ancient river channel incised into the Great Barrier Reef shelf, Australia, using a vessel-mounted multibeam sonar system. Grid pixel resolution is 5 m. Total grid distance is about 8 km.

dangers to vessels conducting multibeam surveys, and so lidar has been used to successfully map large areas of continental shelf where vessel surveys would be impracticable (Figure 2).

### Examples

The development of the various swathe mapping technologies represents an evolution in the ability to image large areas of the seafloor in nearly as high a detail as found in aerial photographs of land (Wille, 2005). For state mapping agencies, these advanced technology mapping tools provide the density of soundings to detect fine-scale shoal features that pose risks to maritime navigational safety (see Australian Hydrographic Service; <http://www.hydro.gov.au/aboutus/what.htm>). For industrial and scientific purposes, this evolution in ocean mapping technology reveals the true shape and geological nature of the seafloor (Figure 3). For coral reef environments, swathe mapping has provided new insights about the geomorphology of coral reefs and the inter-reefal seafloor beyond the limits of scuba diving (e.g., Grigg et al., 2002; Finkl et al., 2005; Beaman et al., 2008; Brock et al., 2008; Webster et al., 2008). Combined with other remote sensing techniques, such as sub-bottom profilers and towed sidescan sonar, and optical and sediment ground-truth methods, the detailed seabed habitat maps are a fundamental first step on which to base management decisions about coral reef ecosystems (see Pacific Islands Benthic Habitat Mapping Center; <http://www.soest.hawaii.edu/pibhmc/>).

### The future

Future improvements in swathe mapping technology will increasingly see multibeam sonar systems mounted on underwater vessels, such as remote operated vehicles (ROVs) and untethered autonomous underwater vehicles (AUVs; Mayer, 2006). The advantage of taking a multibeam system closer to the seafloor are improvements in the quality of acoustic returns, but these methods also provide engineering challenges for the accurate positioning and orientation of the vessel within the water column. Other mapping advances will see greater use of multifrequency (hyperspectral) acoustic and laser transmissions which allow improved generation of co-registered seafloor reflectance (substrate) imagery, as well as mid-water feature detection, such as schools of fish and gas seeps. Advances in the development of interactive 3D visualization software will also be seen in order to facilitate the interpretation and analysis of these large, complex, multicomponent spatial datasets (Mayer, 2006).

Additional future challenges are more political in nature. Developed nations with access to these tools will need to provide greater assistance to developing coastal nations, many of which have jurisdiction over vast ocean areas with sensitive coral reef environments. These developing nations often lack the human resources, mapping skills, and equipment to help solve their own environmental problems, and therefore developed nations must assist in the technology transfer to generate the spatial datasets necessary for informed coral reef management decisions (see Pacific Islands Applied Geoscience Commission; <http://www.sopac.org/homepage>).

**Swathe Mapping, Figure 2** Lidar mapped Ribbon Reefs in the northern Great Barrier Reef, Australia. The gaps in data coverage are inter-reefal areas where seabed depths lie greater than about 50 m, the limits of laser penetration into the water column. Grid pixel resolution is 25 m. Total grid distance is about 110 km.

**Swathe Mapping, Figure 3** An example of a multibeam swathe mapping survey over Emily Reef, a broad coral reef platform on the northern Great Barrier Reef, Australia. Grid pixel resolution is 5 m. Total grid distance is about 8 km.

## Conclusion

Swathe mapping techniques, such as multibeam and lidar, have provided an evolution in mapping of the world's oceans over the past few decades. For tropical coral reefs, swathe mapping provides greater understanding about the true nature of the deeper seabed and inter-reefal habitats. These new discoveries are guiding major advances in energy extraction, fisheries resource management, and environmental protection of the sea. Developed nations with access to these tools must provide technology transfer to the developing coastal nations that have jurisdiction over sensitive coral reef environments, but still lack the human resources, mapping skills and equipment to help solve their own environmental issues.

## SYMBIOSIS

Andrew C. Baker

University of Miami, Miami, FL, USA

## Synonyms

Mutualism

## Definition

The close and usually long-term interaction between members of different biological species. From the greek words *syn* (together) and *biosis* (living): “living together.”

Originally introduced by Anton de Bary in 1879 to refer to “the living together of differently named organisms,” symbiotic relationships include mutualisms (in which both partners mutually benefit from the interaction), parasitisms (in which one partner benefits at the expense of the other), and commensalisms (in which one partner benefits and the other partner is unaffected). However, in both scientific literature and the vernacular, “symbiosis” is often used to refer strictly to mutualistic interactions (Wilkinson, 2001).

Symbioses (including mutualisms, parasitisms, and commensalisms) are particularly common on modern coral reefs, where species densities and the incidence of coevolved relationships are extraordinarily high. Perhaps the most critical mutualistic symbiosis on modern coral reefs is that between scleractinian reef corals and dinoflagellates in the genus *Symbiodinium*, commonly referred to as “zooxanthellae.” These algal symbionts live in the gastrodermis of the coral (hence are “endosymbionts”) at densities that typically reach 1–2 million per square centimeter of coral tissue, and pass >90% of the energy-rich products of their photosynthesis (photosynthate) to their host (see Chapter *Zooxanthellae*). This mutually beneficial arrangement drives the high productivity found on coral reefs and sustains the rapid calcification and growth of corals that in turn build the reef and create the habitat which supports the high biodiversity characteristic of these ecosystems (Muscatine and Porter, 1977). Mutualisms involving reef corals and Bacteria are also a growing area of symbiosis research, with some Bacteria hypothesized to benefit coral hosts by, for example, producing antibiotics (Reshef et al., 2006).

Another example of a common mutualistic symbiosis on reefs is that of “cleaning stations”, where small fish (*Labroides* spp.) and shrimp remove parasites from the body, mouth, and gills of larger fish. Cleaners are recognized by their bright coloration patterns and behaviors, and large fish congregate at cleaning stations – usually coral outcrops or other prominent reef features – to benefit from these services (Grutter, 1999). Other well-studied examples of coral reef mutualisms include the association between clown fish (*Amphiprion* spp.) and large sea anemones. The clown fish (and some other related species in the genera *Premnas* and *Dascyllus*) do not trigger the anemone's stinging response, and receive protection from

predators by using the anemone as a home base. In return, the bright colors and aggressive behavior of the fish attract other fish, which then become potential prey for the anemone.

## TAHITI/SOCIETY ISLANDS

Lucien F. Montaggioni  
University of Provence, Marseille Cedex 3, France

### Definition

The Society Islands are a group of aligned volcanic islands in the south Pacific, with Tahiti as the main island. Their name is usually thought to have been attributed by Captain James Cook in honor of the Royal Society of London. Politically speaking, these islands are part of the French Polynesia.

### Environmental setting

Located in the southern Pacific Ocean between 17°52'S–148°4'W and 15°48'S–154°32'W, the Society Islands are subdivided from southeast to northwest into the Windward Island Group (Mehetia, Tahiti, Moorea, Maiao, Tetiaroa) and the Leeward Island Group (Huahine, Bora-Bora, Raiatea, Tahaa, Maupiti, Tupai, Mopelia, Scilly, Bellinghausen). They result from the activity of a volcanic hot spot at present located close to Mehetia at the southeastern end of the island chain. The high volcanic islands increase in age from less than 0.3 to about 5 million years along a southeast–northwest axis (Guillou et al., 2005). Except for Mehetia, all these islands are surrounded by fringing and/or barrier reefs. The low-lying coral islands (atolls) include Tetiaroa, Tupai, Mopelia, Scilly, and Bellinghausen.

### Coral diversity and distribution

Compared to the world's richest Indonesian center, the scleractinian coral fauna at Tahiti and in the nearby islands appears substantially depauperate. The number of reef-building coral genera in the region does not exceed 35. Additionally, species richness varies substantially from

zone to zone. Species richness and coral cover rate decline from the open sea shorewards. Along fore-reef slopes, the coral pool contains up to 25 species. By contrast, in reef-crest and reef-flat zones, the number of species is less than 20 (Karlson et al., 2004).

The composition of the reef coral communities has been quantitatively analyzed in Moorea and regarded as exemplifying that of the Society high volcanic islands (Bouchon, 1985). Fringing reef flats are typified by paucispecific assemblages with massive, branching, and foliaceous forms (*Porites lutea*, *P. (Synarea) rus*, *Montipora circumvallata*, *Pavona cactus*). Barrier reefs exhibit higher diversity communities. The barrier reef flats are dominantly composed of robust branching, arborescent, and laminar acroporids (*Acropora abrotanoides*, *A. robusta*, *A. nobilis*, *Montipora erythraea*, *M. verrucosa*), pocilloporids (*Pocillopora verrucosa*, *P. damicornis*), and massive poritids (*Porites lobata*, *P. lutea*). The backreef zones are colonized preferentially by tabulate and laminar acroporids (*Acropora cytherea*, *Montipora erythraea*) and massive poritids. Along the fore-reef slopes, three distinct assemblages can be identified. The deeper fore-reef assemblage (>30 m) consists mainly of poritids (*Porites*, *Synarea*), faviids (*Leptastrea purpurea*, *Favia stelligera*), and agariciids (*Pachyseris speciosa*). The intermediate assemblage (15 to >20 m) is typified by poritids (*Napopora irregularis*) and faviids (*Montastrea curta*, *Leptastrea transversa*) together with agariciids (*Gardineroseris planulata*). The upper fore-reef community (<10 m) prominently contains acroporids (*A. humilis*, *A. intermedia*, *A. variabilis*, *Montipora erythraea*) and pocilloporids (*Pocillopora eydouxi*, *P. verrucosa*).

The coral distribution on the Society atolls is very close to that described from the high islands. Some differences are observed only in the composition of lagoonal patches. These are made up of *Pseudocolumastrea*, *Pavona*, *Stylophora*, *Stylocoeniella*, *Acanthastrea*, *Platygyra*, *Astreopora*, *Cyphastrea*, and *Psammocora*, associated with ubiquitous

forms (*Porites lobata*, *Leptastrea*, *Acropora* spp., *Pocillopora*). The reef-crest settings usually show a typical algal ridge about 0.5–1 m in elevation and dominantly composed of coralline algae (*Hydrolithon onkodes*, *Porolithon craspedium*). The coral coverage ranges from 2% to less than 10% of the substrate area. Corals include pocilloporids and robust acroporids.

### Stratigraphy, lithology, and growth history of late Pleistocene to Holocene reefs

The studies devoted to the internal structure and growth history of the Society Island reefs began with the use of subsurface drilling in the 1970s. Most of the drilling investigations have been conducted on Tahiti Island both through modern barrier reefs at sea level (Montaggioni, 1988; Cabioch et al., 1999) and submerged buildups at present located at 42–118 m water depth (Camoin et al., 2007). Uranium series dating of corals indicate that both coral reef systems consist of two distinct lithological sequences: a last deglacial sequence (Bard et al., 1996; Camoin et al., 2007) and an older Pleistocene sequence (Thomas et al., 2009).

#### The last deglacial sequence

This sequence started to deposit at about 16,000 calendar years BP and is 85–93 m in maximum thickness. The reef piles beneath the modern outer barrier reef flat are dominantly composed of rigid coralline frameworks thickly encrusted with microbialites, locally associated with vermetids and encrusting foraminifera or interbedded with detrital material (*Halimeda* plates mainly). Four main coralline assemblages have been delineated from base upwards: a branching/encrusting *Porites* (*P. nigrescens*, *P. lichen*) assemblage mainly encrusted with branching coralline *Lithophyllum* and *Mesophyllum*; a massive *Porites* (*P. lobata*, *P. lutea*) assemblage usually associated with branching *Lithophyllum* and *Dermatolothon*; a tabular branching *Acropora* (*A. hyacinthus* group, *A. clathrata*) assemblage with massive *Montastrea annuligera*, encrusted with millimeter-thick crusts of *Neogoniolithon* cf. *absimile*, *N.* cf. *propinquum*, *Dermatolothon* cf. *tesselatum*, and *Mesophyllum prolifer*; and a robust branching *Acropora* (*A. robusta* group, *A. humilis*) and *Pocillopora* (*P. verrucosa*) assemblage coated with 2–5-cm-thick veneers of *Hydrolithon onkodes* and *Neogoniolithon fosliei*. By analogy with the habitat depth range of their modern counterparts, these coralline communities are assumed to form a succession that reflects an upward-shallowing sequence. Furthermore, given that the robust branching *Acropora*–*Hydrolithon onkodes* assemblage usually occupy 50–85% of the total core length, the barrier reef top is thought to have maintained pace with the rising sea level during the main phases of reef accretion (keep-up growth mode).

The reef piles beneath the submerged buildups present strong similarities in composition to those described from the barrier reef. In addition to the four coralline communities delineated above, there have been found foliaceous

and laminar coral assemblages mainly composed of deep-water forms (*Montipora*, *Pachyseris*, *Echinophyllia*, *Leptoseris*) locally associated with a variety of ubiquitous genera (*Porites*, *Leptastrea*, *Astreopora*, *Psammocora*). These colonies are coated with millimeter-thick coralline algal crusts (mostly *Dermatolothon*, *Mesophyllum*, and *Lithophyllum*) in association with microbialites to form loose frameworks. This deep-forereef assemblage usually occur at the uppermost part of the core sections. Thus the coralline succession appears to be reversed compared to that of the barrier reef. This expresses upward-deepening conditions (give-up growth mode) in relation to a reef drowning event.

Microbialites are one of the major components of the deglacial reef sections, locally representing up to 80% of the reef rock (Montaggioni and Camoin, 1993; Camoin et al., 1999; Camoin et al., 2007). They have been encountered at all depths in the test areas and range in age from about 16,000 to 4,500 calendar years BP. Microbialites occupy the primary cavities within the reef rock and usually form a late stage of encrustation over coralline frameworks. They exhibit a suite of typical growth forms ranging from irregular domes and bulbs to columns. Their internal fabrics range from structureless dense micrite to clotted aggregates, resulting in two end-members represented by microbial laminae and thrombotic to dendritic structures. Composed of high-magnesian calcite with 7–16 mole%  $MgCO_3$ , they have developed principally through the activity of heterotrophic bacteria.

The coralline assemblages recognized in the Tahiti cores have been used as reliable paleodepth indicators. A coral-based sea-level curve has been reconstructed for the past 16,000 years (Bard et al., 1996; Camoin et al., 2007). Analysis of the curve indicates the presence of hiatuses in reef growth at around 14,000 calendar years BP. This provides strong support for a rapid sea-level jump interpreted as triggered by an important meltwater pulse (MWP-1A). By contrast, no detectable meltwater surge has been recorded in the reef cores at around 11,500 (MWP-1B) and 8,200–7,600 (8.2 ka event) calendar years. Sea level appears to have approximated its present position at around 6,500 calendar years.

#### The older Pleistocene sequence

The unconformity between the last deglacial and older Pleistocene sequences ranges in depth between 87 and 122 m below present sea level. Several successive unconformities are identified in the upper sections of the older Pleistocene sequence, indicating the superimposition of successive reef bodies. This is confirmed by chronostratigraphy. Uranium–thorium dating of pristine coral samples (Thomas et al., 2009) reveal active reef growth respectively between 153,400–152,700 years BP (Marine Isotope Stage (MIS) 6), 137,800–136,900 years BP (transition MIS 6–5), and 33,000–29,600 years BP (MIS 3). The older Pleistocene sequence is similar in composition to that of the last deglaciation. It is made up of several depth-related coralline

assemblages respectively dominated by tabular *Acropora*, massive *Porites*, encrusting *Montipora* and *Pachyseris*, and coated with thick microbialite crusts.

### Emerged reefs and related features

The Society Islands exhibit high sea-stand indicators including in situ emerged microatolls, abandoned algal ridges, and conglomerates. These give evidence of a mean sea-level standstill at a maximum elevation of +1.0 m between 5,000 and 1,200 years BP as a result of the postglacial hydro-isostatic adjustment. However, there are significant differences in the present elevation of the mid-Holocene shorelines between the Leeward and Windward Islands. The elevation ranges from about +1.0/+0.8 m from Scilly to Huahine to +0.5/+0.3 m in Tahiti and Moorea. This strongly suggests that since 3,000 years BP, Tahiti and Moorea have undergone a gradual subsidence at a rate of about 0.15 mm yr<sup>-1</sup>, which is interpreted as caused by a differing lithospheric flexuring along the island chain (Pirazzoli and Montaggioni, 1988).

There is no evidence of Pleistocene high sea stands regionally.

### Coral paleoclimatology

The measurement of growth characteristics over the last two centuries on *Porites* colonies collected from Moorea Island indicates that the average linear extension and calcification rate have increased significantly in response to increasing sea-surface temperature. The growth records show oscillatory modes at periods of about 21.9 and 4.5–6.6 years, respectively, attributed to changes in El Niño-Southern Oscillation and solar radiation (Bessat and Buigues, 2001). The regional record of a recent increase in sea-surface temperature is consistent with coral oxygen isotope data (Boiseau et al., 1998).

### Summary

The Society Islands, including Tahiti, form a linear chain of volcanic islands rimmed by fringing to barrier reefs and locally forming atolls. The coral diversity does not exceed 35 genera. Acroporids, pocilloporids, and poritids are the most common reef builders irrespective of island. Algal ridges are usual reef-crest features. The world's thickest continuous reef sequence encompassing the last deglacial times has been extracted from the Tahitian barrier reef. Late Pleistocene to Holocene reef frameworks are typified by the general occurrence of thick microbialite crusts. There are exposures of mid- to late Holocene reef-related deposits in most of the islands, providing evidence of a high sea stand at a maximum elevation of +1 m.

## TAPHONOMY

Benjamin J. Greenstein  
Cornell College, Mount Vernon, IO, USA

### Definition

Taphonomy is the systematic study of the processes that affect organic material, including skeletons, postmortem.

### Introduction

The geologic subdiscipline of Taphonomy was introduced originally by Efremov (1940) to include the study of the processes involved in the transition of organic remains from the biosphere to the lithosphere. Over a five-decade interval (~1920–1970), numerous German researchers at the Senckenberg Research Institute of Marine Biology and Marine Geology on the North Sea carried out classic investigations of processes of decay, disarticulation, and burial affecting organisms in shallow marine environments. The results of those studies (Aktuo-paläontologie or “Paleontology of the Recent”) were compiled by Schäfer (1972) into a landmark volume. A generation of paleontologists in North America and the former Soviet Union subsequently began to elucidate and quantify the ecological information lost as organisms were subjected to a variety of physical, biological, and chemical processes prior to their final entombment within the sediment and subsequent discovery as fossils (e.g., Lawrence, 1968; Schopf, 1978). The results of such studies typically were issued in the form of a caveat to any researcher seeking to reconstruct communities based on the fossil record. This body of research is generally referred to as the “information loss” approach to taphonomic studies.

Research reports published in a taphonomy theme issue of the *Journal Palaios* (1986) demonstrated clearly that taphonomic processes that remove ecological information from the fossil record themselves yield preservable signatures characteristic of specific sedimentary environments and processes of deposition (e.g., Brett and Baird, 1986). This “information gain” approach to Taphonomy catalyzed another generation of paleontologic research that applied modes of preservation to paleoenvironmental reconstruction and temporal resolution of fossil assemblages and has dominated the literature over the last quarter century (extensive reviews are given in Allison and Briggs, 1991; Donovan, 1991; Martin, 1999, and Behrensmeyer et al., 2000).

### Reef coral taphonomy

Relative to other marine invertebrates that possess potentially preservable hard parts, coral preservation has received attention from paleontologists relatively late in the history of the subdiscipline. Although Martindale (1984) and Scoffin (1992) reviewed the salient taphonomic processes operating in coral reef environments, taphonomic research on the most important component of reef structures, the corals themselves, was largely lacking until the mid-1990s. Despite its relatively late appearance,

taphonomic research on coral reefs (for reviews see Greenstein, 2007; Perry and Hepburn, 2008) expanded rapidly in parallel with (and, in part, to justify) the increasing use of the Quaternary fossil record of coral reefs to better understand the various disturbances currently affecting modern reefs. The burgeoning reef taphonomic literature has documented a variety of important results which fall into five general categories: (a) sources of taphonomic bias affecting corals, (b) fidelity of coral death assemblages to life assemblages, (c) comparisons of the taxonomic composition of coral life, death and fossil assemblages, (d) using taphonomically important organisms and/or processes to determine depositional environments and history of reef framework accumulation, and (e) application of taphonomic and paleoecological data to provide a geological context for the current reef crisis (Table 1).

### Taphonomic bias

Studies of taphonomic bias affecting corals involve systematic quantification of a variety of features produced while dead colony skeletons reside on the sea floor. Although many of these features may either add carbonate material (e.g., encrusting skeletons of epibiont organisms) or remove it (e.g., borings made by a variety of endobiont organisms) all have the effect of inhibiting the potential for identification of a coral taxon. Several studies have investigated the roles that coral colony growth form and reef environment play in determining preservation potential of corals present in death assemblages of the Great Barrier Reef (Pandolfi and Greenstein, 1997a) and the tropical Western Atlantic (Greenstein and Pandolfi, 2003; Gardiner et al., 2005) regions. Perry (1998) elucidated the environmental distribution of macro-boring organisms (and hence, preservation potential of the affected coral skeletons) in adjacent reef environments across a barrier reef system in Jamaica. Results of these studies indicate that preservation potential is highly variable between reef environments and also that higher diversity coral assemblages (particularly acroporid corals with branching colony growth forms) in the Indo-Pacific region may suffer particularly from taphonomic bias.

### Fidelity

Fidelity refers to the degree to which any fossil assemblage reflects the taxonomic composition of a once-living assemblage (see Kidwell and Bosence, 1991). In marine environments, fidelity studies, typically, are conducted by systematically sampling and identifying live and dead organisms occurring in and on the substrate. An implicit assumption of these types of studies is that the death assemblage represents the “first step” in the transition of a living assemblage of organisms into the fossil record (Greenstein, 2007), although for corals, this may not be the case (Edinger et al., 2001).

Fidelity studies of coral assemblages began with comparisons of live and dead reef coral assemblages by Pandolfi and Minchin (1995) on fringing reefs in Madang Lagoon, Papua New Guinea. Live–dead comparisons of

coral assemblages were subsequently performed on shallow and deep reefs of the Florida Keys by Greenstein and Pandolfi (1997) and Pandolfi and Greenstein (1997b), respectively. These studies revealed complex patterns of fidelity at inter- and intraprovincial scales.

### Comparisons of life, death, and fossil assemblages

The over-arching rationale for coral taphonomic research is a better understanding of the fossil record (Greenstein, 2007). As mentioned above, work on modern coral death assemblages assumes that they provide a reasonable proxy for an eventual fossil assemblage. Comparative studies of coral life, death and fossil assemblages have tested this assumption by including Late Pleistocene (e.g., Greenstein et al., 1998a) or Holocene (Edinger et al., 2001) fossil coral assemblages exposed near localities where modern life and death assemblages are examined. In general, these studies have ascertained that the assumption of a stepwise transition from live to dead to fossil coral reef assemblages is largely false: reef coral death assemblages, generally, are not reasonable proxies for fossil assemblages. Rather, living reefs (i.e., coral colonies that are buried whilst alive) and the death assemblages associated with them apparently are preserved in Pleistocene and Holocene strata.

### Interpretation of depositional environments

A great deal of actualistic (i.e., conducted in modern environments) taphonomic research has revealed the spatial and bathymetric distribution of organisms and physical

environmental processes that leave preservable remains on or in coral skeletal material (see Perry and Hepburn, 2008 for an excellent review). This body of literature shows clearly that “taphonomic signatures” may be used to discriminate between reef subenvironments as well as the history of reef framework accumulation. Such studies are particularly useful for focusing environmental interpretations made from coral material present in cores (e.g., Aronson and Precht, 2001; Blanchon and Perry, 2004). Examination of ecological successions of endo- and epibionts on fossil coral material allowed Perry (2001) to distinguish between layers of reef framework that accumulated via event (storm) deposition from those that represented gradual reef accretion. The refinements in environmental interpretation made in this fashion also have been used to constrain the upper limits of a widely cited Holocene sea level curve (Toscano and Macintyre, 2003) and interpret past incidences of coral mortality events (e.g., Aronson and Precht, 1997; Greenstein et al., 1998a, b; Aronson and Precht, 2001; Hubbard et al., 2005; Aronson et al., 2005).

### Applications to modern reef ecology

Late Pleistocene and Holocene fossil reef coral assemblages are usually exceptionally well preserved (Greenstein and Moffat, 1996; Greer et al., 2009) and contain coral species virtually identical to those living today (Budd et al., 1994). Moreover, Late Pleistocene reefs were thriving during an interval of rapid and dramatic climate fluctuations

(e.g., Pandolfi, 1996). Thus fossil coral assemblages from these time intervals preserve a particularly useful historical record of the response of reef coral communities to an array of ecological and environmental perturbations that occurred in the absence of anthropogenic disturbances. An ever-expanding body of work has sought to establish whether many of the crises affecting modern reefs (e.g., large scale bleaching events, the Caribbean-wide die off of *Acropora cervicornis*, “phase shifts” to alternative reef-dominant taxa) have historic (prehuman) precedents. In numerous studies, Aronson and colleagues (Aronson and Precht, 1997, 2001; Precht and Aronson, 1997; Wapnick et al., 2004; Aronson et al., 2005) have demonstrated that the recent mass mortality of *A. cervicornis* (and in some places its subsequent replacement by a different coral taxon) had no precedent in at least the last 3,800 years in Belize and 1,200 years in Jamaica. Hubbard et al. (2005) described 7,000 years of dominance of the now decimated Caribbean reef crest indicator species *Acropora palmata* in cores obtained from reefs adjacent to St. Croix, US Virgin Islands, although two millennial scale gaps also were identified and attributed to a wider Caribbean phenomenon. Greer et al. (2009) demonstrated the continuous accumulation of *A. cervicornis* over several millennia in Holocene deposits from the Dominican Republic. Examples of coral persistence also have been drawn from Pleistocene deposits in the Caribbean (e.g., Jackson, 1992; Greenstein et al., 1998a) and Indo-Pacific (Pandolfi, 1996) regions. All of these studies point out the stark differences between the historical records of these taxa and their recent declines.

## Conclusion

Studies of taphonomic processes operating in coral reef environments have identified the various mechanisms that serve to remove ecological data from the fossil record. However, much of the literature represents the “information gain” approach to Taphonomy, and has applied taphonomic analyses to refine one’s understanding of the nature of the reef stratigraphic record. Perhaps most important, taphonomic research has underscored the fact that studies of Late Pleistocene and Holocene reef coral paleoecology are essential components of one’s understanding of the crises currently affecting the global reef system.

## TEMPERATURE CHANGE: BLEACHING

---

Tom Spencer  
 University of Cambridge, Downing Place,  
 Cambridge, UK

## Definition

Corals respond to thermal stress and synergistic increases in solar irradiance, by whitening or bleaching, a process reflecting the loss of color in symbioses between dinoflagellate algae of the genus *Symbiodinium* and corals.

## Introduction

Sea surface temperatures increased globally by  $0.52 \pm 0.19^\circ\text{C}$  between 1850 and 2004 (Rayner et al., 2006). Based on an earlier dataset, Lough (2004) demonstrated how temperatures had increased by  $+0.17^\circ\text{C}$  over the period 1951–1990 at 16 coral reef sites in the Pacific Ocean, Indian Ocean and Red Sea, an accelerated rate of change not paralleled in the earlier historical record. It has been argued that this ocean warming has moved corals closer to their thermal maxima, with warmer than average years pushing corals over the threshold of thermal tolerance (e.g., Hoegh-Guldberg, 1999). Corals respond to thermal stress and synergistic increases in solar irradiance, by whitening or “bleaching.” Bleaching is the visible sign of the degeneration and/or loss of dinoflagellate symbionts (zooxanthellae), and/or the loss of cells containing these symbionts, from coral tissues as photo-protective mechanisms are lost. The dinoflagellates play a key role in coral metabolism and their reduced function or loss, is accompanied by reduced carbon fixation, coral growth and reproductive ability (Hoegh-Guldberg et al., 2007). There is a perception that bleaching is fundamentally an unnatural phenomenon but symbioses generally display seasonal variation in the density and pigment content of algal cells, with minimal values at the end of the season with the highest sea water temperatures (e.g., Brown et al., 1995; Fagoonee et al., 1999; Fitt et al., 2000); bleaching intensity is an extension of this normal process, with its severity following the length and severity of the warming phase. At the scale of the coral ecosystem, the implications of coral bleaching include significant reductions in the cover of those susceptible species that die *en masse*, changes that occur in community composition and decrease in species and habitat diversity (e.g., Hughes and Connell, 1999). In some circumstances, following mass coral mortality (Figure 1), the dominant benthic cover may switch to a macro-algal community, indicating a phase-shift from a hard to a soft reef (Done, 1992).

**Temperature Change: Bleaching, Figure 1** Appearance of a shallow coral area dominated by *Acropora* corals show that they are (a) normal, (b) bleached, and (c) dead and covered with a low algal community. Photo credits. Australian Institute of Marine Science: (a) and (c) Eric Matson; (b) Ray Berkelmans.

Major coral bleaching events took place in 1982–1983, 1987–1988, 1994–1995 and particularly in 1997–1998 (Figure 2) when, it has been claimed, that 16% of the world's reef-building corals were killed (Walther et al., 2002).

There has been a marked upturn in the record of bleaching events from all the major reef provinces in the 1980s which are difficult to explain solely by improved reporting (Glynn, 1993). One argument, therefore is that the appearance of these impacts represent an early signal of global warming in the oceans, with ENSO triggers to bleaching being superimposed on a secular trend of rising sea-surface temperatures (Figure 3) (Williams and Bunkley-Williams, 1990; Hoegh-Guldberg, 1999).

### Geographical patterns of bleaching

Bleaching can be induced by a variety of stressors but thermal stress has been implicated in both local (Figure 4) and large-scale bleaching events (Figure 2) (e.g., Fitt and Warner, 1995; Glynn, 1996; Brown, 1997). The correlation between high sea surface temperature anomalies and bleaching events has enabled the tracking of bleaching hotspots – reef areas where bleaching is likely to occur as a result of temperatures over the usual monthly maxima (Goreau and Hayes, 1994; Strong et al., 1997). In some situations, however, temperature is not an infallible guide to likely bleaching impacts: thus local cloud cover conditions in 1998 in the Society Islands, S.W. Pacific (Mumby et al., 2001) and in Mauritius, W. Indian Ocean (Turner et al., 2000) may have saved these reefs from more severe bleaching impacts at a time of widespread ocean warming. As bleaching is generally correlated with short hot spells rather than mean water temperatures (Berkelmans et al., 2004), the refinement of this approach through the development of indices which look at the time period of heating above a critical thermal threshold, such as Degree Heating Week (DHW; Strong et al., 1997) and Degree Heating Month (DHM), has been effective.

Bleaching associated with up to several weeks of temperature elevations of +1 to +2°C above regional seasonal maxima is often species- and/or reef location-specific and repaired after a few months with little coral mortality. This process is achieved by the repopulation of coral tissues by zooxanthellae that remain in the host. Although numbers may be two to three orders of magnitude less than in healthy corals, bleached corals may nevertheless contain up to 10,000 dinoflagellates cm<sup>-2</sup> (Hoegh-Guldberg and Smith, 1989). However, large temperature excursions of +3 to +4°C, particularly if they are prolonged, can produce mass bleaching of entire reef communities and subsequent coral mortality rates in excess of 90% (e.g., Douglas, 2003; Hoegh-Guldberg et al., 2007).

Whilst satellite temperature is well correlated with field temperature measurements and bleaching incidence when aggregated over space and time, such correlations often break down at the scale of individual reef systems (McClanahan et al., 2007). Indeed, bleaching can be very patchy in time and space, sometimes down to the scale of the individual coral colony. Key environmental factors include light regime (Coles and Jokiel, 1978; Anthony et al., 2007), wave activity (Nakamura and van Woesik, 2001; Nakamura et al., 2003) and thermal microclimates.

**Temperature Change: Bleaching, Figure 2** Global variations in bleaching intensities, 1997–1998 bleaching episode (with permission from UNEP-WCMC).

**Temperature Change: Bleaching, Figure 3** Model of the causes of world-wide coral bleaching (after Williams and Bunkley-Williams, 1990).

Local hydrodynamics, in the form of upwelling of cooler deep waters along reef fronts, wave- and tidal-driven current flows on fore-reefs and long water residence times in lagoons with restricted tidal exchange, can all strongly influence patterns of bleaching incidence (e.g., McClanahan et al., 2005), along with variations in water turbidity and variations in coral resilience imposed by differential human impacts.

#### Variability in coral sensitivity to thermal stress

Sensitivity of corals to thermal stress can be highly variable between species (e.g., Gleason, 1993; Brown and Surharsono, 1990; Loya et al., 2001) and even between populations within individual species (e.g., Ulstrup et al., 2006). Thus, for example, during the 1998 bleaching event on the Great Barrier Reef, the hydrocorals (*Millepora* spp.) were the worst affected (85% mortality),

**Temperature Change: Bleaching, Figure 4** (upper) General relations between sea surface temperatures and major bleaching episodes. (lower) Coral bleaching and sea surface temperature, fringing reef, north coast of Moorea, Society Islands, S.W. Pacific Ocean. Temperature measured *in situ* at 14 m water depth; solid line = monthly mean temperature; dotted line = maximum temperature for each month; horizontal dashed line = bleaching threshold temperature of 29°C (after Hoegh-Guldberg and Salvat, 1995).

acroporids and pocilloporids severely affected (18–38% mortality) but poritids and faviids (0–2% mortality) barely impacted at all (Marshall and Baird, 2000).

It is well known that coral populations from warmer waters can withstand higher temperatures compared to populations of the same species that live in cooler waters (e.g., Coles et al., 1976). Furthermore, Berkelmans and Willis (1999) have described the winter thermal limit for *Pocillopora damicornis* on the central Great Barrier Reef as being 1°C lower than the temperature threshold for the same coral species in summer. Developed from these observations is research that suggests that corals, may be able to acclimate (an individual, physiological response) or adapt (a genetic response at the population level) to changed thermal regimes, particularly as a result of shifts in coral host – dinoflagellate relations, creating “new” ecospecies with tougher environmental tolerances and supporting more temperature tolerant strains of zooxanthellae, an idea first put forward by Buddemeier and Fautin

(1993) under the term Adaptive Bleaching Hypothesis. There are several examples of coral hosts containing more than one genetic variety of *Symbiodinium*; and some clades appear correlated with potentially more stressful environmental conditions than others (Rowan et al., 1997). Thus the “type D” symbiont has been shown to confer an additional 1.0–1.5°C tolerance in *Acropora millepora* compared to “type C” (Berkelmans and van Oppen, 2006). In such circumstances, there is likely to be an increase in the thermal threshold to bleaching, a hypothesis supported by field observations which show that past-bleaching episodes can indeed provide corals with some measure of resistance to subsequently raised temperatures (e.g., Brown et al., 2002; Baker et al., 2004). There is potentially a spectrum of coral responses, from the “shuffling” of the relative abundance of symbionts within a coral colony, to the “switching” of symbionts by externally-derived symbionts new to the colony (but not the coral species), to full “evolutionary switching” where

**Temperature Change: Bleaching, Figure 5** Alternative hypotheses concerning the threshold sea surface temperature at which coral bleaching occurs: (a) invariant threshold for coral bleaching = solid line) which occurs when sea surface temperature exceeds usual seasonal maximum threshold (by ca. 1°C) and mortality (dashed line, threshold of 2°C), with local variation due to different coral species or water depth; (b) elevated threshold for bleaching (solid line) and mortality (dashed line) where corals adapt or acclimatize to increased sea surface temperature (from Nicholls et al., 2007, after Hughes et al., 2003).

the host acquires symbionts which have not before been supported by the coral species (Baker, 2001, 2003; Coles and Brown, 2003; Hoegh-Guldberg et al., 2007).

### Summary: Temperature change and coral reef futures

The application of sea surface temperature – bleaching relations to the temperature trends seen in large ocean temperature datasets implies that the threshold temperature at which corals bleach will occur more frequently in the near future, potentially to the point on some reefs where bleaching is an annual event. Such scenarios have been used to drive “time to reef extinction” models (e.g., Hoegh-Guldberg, 1999; Sheppard, 2003). However, not only do the extinction-type models fail to allow for the small-scale patterning of temperature impacts (and thus the possibility of coral survival for re-population within local refugia) but they also fail to take account of the potential adaptive responses of corals and/or their algal symbionts to temperature change (both past and predicted) (Figure 5; Hughes et al., 2003).

It seems more likely, therefore, that the links between coral bleaching and global environmental change will lead to the patchy reorganization of coral communities and the degradation of ecosystem function and diversity rather than complete coral reef loss (Figure 5).

## TETHYS OCEAN

---

Rachel Wood

Grant Institute University of Edinburgh, Edinburgh, UK

## Definition and introduction

The Tethys was an ancient ocean that existed from 250–~50 million years ago before the evolution of the Indian Ocean. Tethys was orientated east–west and separated the large continents of Gondwana and Laurasia. It was named after the ancient Greek goddess of the sea by Eduard Suess in 1893,

who inferred the presence of a huge ocean using the record of marine fossils from the Alps and Africa.

Many of the Earth's tropical continental shelves at this time were found around the margins of the Tethys Ocean, making the Tethys host to many reef ecosystems for a considerable part of the Mesozoic and into the Cenozoic. At its greatest extent, the Tethys Ocean was part of a continuous series of oceans that covered the Earth between  $\sim 30^\circ\text{N}$  and the Equator, creating circulation patterns quite unlike those known today.

## History

In late Permian times ( $\sim 280$  Ma), the continents were coalesced into one huge landmass known as Pangaea. The C-shaped form of Pangaea enclosed an ocean known as Palaeo- or Neo-Tethys. By the Early Triassic ( $\sim 240$  Ma), an extensive sea-floor spreading ridge (rift) had developed along the northern continental shelf of Southern Pangaea, forming a new ocean along the southern shore of Neo-Tethys. This rift extended from Australia at the southeast corner of Pangaea northwest to the meeting point of the plates of Africa, North America, and Europe. Continued rifting formed an ocean basin bounded to the south and west by the plates of Pangaea and to the north and east by the newly formed microplates of Turkey, Iran, and Tibet. These microplates migrated rapidly northward toward the plates of Eurasia and China, eventually enclosing Neo-Tethys. The Tethys Ocean continued to expand westward, dividing Pangaea into the two large continents of Laurasia in the north and Gondwana in the south, creating an oceanic extension of the Tethys, which today forms the central Atlantic Ocean. Subsequently, the continental shelf known as Cimmeria, traveled north and was, then, subducted beneath the oceanic crust of the Neo-Tethys Ocean under Laurasia, forming the Tethyan Trench. The Mesozoic Tethys Ocean so formed between Cimmeria and Gondwana, over the area occupied by Neo-Tethys.

Between the Jurassic and the Late Cretaceous ( $\sim 100$  Ma), Gondwana began to break up into smaller

continents, with the Indian and African continents migrating north to create the Indian Ocean (Figure 1). This caused the Tethys Ocean to reduce considerably in area, becoming the Tethys Seaway or the second "Tethys Sea." The Tethys Sea provided a broad marine seaway that connected the Indian and Atlantic oceans until the Miocene.

India, Indonesia, and the Indian Ocean now cover the area once occupied by the Tethys Ocean, and Turkey, Iraq, and Tibet sit on the former continental fragment of Cimmeria. Remnants of the Tethys Ocean include the Mediterranean, Caspian, Aral, and Black Seas (formerly an inland extension of Tethys known as the Paratethys).

## Tethyan reefs

The Tethys was a center of tremendous marine biodiversity, and regional faunal differentiation has been recorded for almost every major period of geological time. Following the end-Permian mass extinction, reef development developed throughout the vast shallow Tethys by the mid-Triassic, in addition to more remote islands in the ancient Pacific, which are now preserved as displaced terranes (a fault-bounded body of rock – sometimes thousands of square kilometers in area – that has been moved from its original position by plate motion). A unique feature found only in the Tethys was the appearance of Permian Lazarus taxa in the Norian, rather than in the preceding Anisian-Ladinian, recovery interval. Late Triassic reefs saw the emergence of scleractinian corals as major reef builders, and this together with a substantial rise in global sea level, allowed for a global expansion of carbonate platforms and high reef biodiversity (Stanley, 1988). Recently, Triassic reefs maximally extended to between  $30^\circ\text{N}$  and  $35^\circ\text{S}$ .

Tethyan reef ecosystems did not show a gradual decline in diversity during the end-Triassic as in other Oceans, but went extinct abruptly at the end of the Triassic. A return to high diversity reefs did not appear until mid-Jurassic time (Stanley, 1988).

**Tethys Ocean, Figure 1** Palaeogeographic reconstructions from the beginning (Late Triassic, 200 million years) toward the end of the Tethys Ocean (Late Cretaceous, 90 million years ago). Red lines mark the major subduction zones. Redrawn from Ron Blakey, NAU Geology.

Even though substantial reefs and carbonates are not common in the Carnian of the western Canadian craton, reef biodiversity was high with more than 50% of known species being also found in Tethys. However, unlike the Tethys, taxa from Norian-Rhaetian terranes are found in lowest Norian rocks. Permian Lazarus taxa are also found in the Norian, and Early Jurassic reefs contain Carnian holdovers, thereby supporting the idea that volcanic islands were refuges in the Panthalassa Ocean during the time when the Tethys Ocean was affected by environmental crises (Stanley, 1988).

During the Jurassic, reefs formed by microbialite, corals, and sponges were widespread along the northwestern margins of Tethys. These reefs occupied shallow- to deep-shelf environments in both pure carbonate and mixed carbonate-siliciclastic settings. Corals were replaced by rudist bivalves in Early Cretaceous reef and carbonate platform communities during a 30 million year period when sea level rose and drowned many continental shelves. Corals appear to have been displaced to the deeper parts of reefs and rudists occupied the shallow, high-energy habitats. By the latest Early Cretaceous, rudists dominated the shallow inner and outer platforms that fringed interior shelf basins, and corals formed reefs together with rudists on the outer shelf margins (Wood, 1999).

After the end-Cretaceous mass extinction, carbonate platforms continued to form on the shores of Tethys. During the Palaeogene, the Earth went through a marked phase of global warming. Between about 60–55 Ma, three stages of carbonate platform development can be identified Tethys-wide (Scheibner and Speijer, 2007). During the first stage, carbonate platforms were populated by corallgal reefs. In the second stage, corallgal reefs thrived only at mid-latitudes and were replaced by larger benthic foraminifera as the dominant carbonate producers in low latitudes. By the early Eocene, newly developed lineages of large foraminifera (“Nummulites”) became the main carbonate-producing biota in low to mid-latitudes. The eventual extinction of the characteristic Palaeo-Mediterranean Nummulite fauna at the end of the Eocene (or in the early Oligocene in eastern Tethys) was apparently accompanied by a global increase in reef coral diversity. The Oligocene represents the height of Cenozoic coral and coralline algal reef development in the western Tethys with maximum abundance, diversity, and cosmopolitan faunas.

## Summary

The Tethys was an ancient east–west ocean that existed from 250 to ~50 million years ago. Many of the Earth’s tropical continental shelves at this time were found around the margins of the Tethys Ocean, making the Tethys host to many reefs for a considerable part of the Mesozoic and into the Cenozoic. The Tethys was a center of tremendous marine biodiversity, and regional faunal differentiation has been recorded for almost every major period of geological time. At its greatest extent, the Tethys Ocean was part of a continuous series of oceans that covered

the Earth between ~30° N and the equator, creating circulation patterns quite unlike those known today.

## TIDAL EFFECTS ON CORAL REEFS

---

David J. Dixon  
 Independent Oceanographer/Geomatics Surveyor,  
 Illogan, Redruth, Cornwall, UK

## Introduction

The gravitational forces of the moon and sun affect not only the astronomical shelf and ocean surface tides but also force tidal currents on the ebb and flood. The dissipation of energy when tidal currents interact with sea bed, shelf features (coral reefs and *Atolls*) produces friction, vertical shears, turbulence, eddies and transfer of energy to other processes such as internal waves and fronts. This has implication in the vertical and horizontal distribution of temperature and nutrients (*Nutrient Pollution/Eutrophication*) beneficial to coral productivity. Tidal resonance may occur in bays and inlets, forcing tidal features quite unlike the oceanic tides, and hence influence reef exposure, solar insolation and coral desiccation.

## Upper limit of coral reefs

The upper vertical limit of corals, coral sand banks, atoll islands (*Atoll Islands (Motu)*), *Reef Flats*, algae (*Algae*, *Coralline*) and sea grass (*Seagrasses*) development are all dominated by tidal ranges.

With many factors influencing the upper limit of coral growth, it is not possible to relate this to a unique tidal level. A more suitable definition is a range of upper growth limit between Mean Low Water Springs (MLWS) and Mean Low Water Neaps (MLWN), (Scoffin, 1977; Hopley, 1982).

Open water coral reef growth is up to MLWS  $\pm 25$  cm whereas *Microatoll* growth is to MLWN, with *moated* lagoon corals as high as Mean Sea Level (MSL) occurring at Redbill Reef (GBR), as observed by Hopley (1986). The *Moating* of corals on reef flats behind high

*Algal Rims* and cemented *Shingle Ridges* allows reef flat corals to survive extreme low tides (Hopley, 1982).

MLWS is defined as  $Z_0 - (M_2 + S_2)$  and MLWN as  $Z_0 - (M_2 - S_2)$  with Mean Low Water (MLW) =  $Z_0 - M_2$ ,  $M_2$ ,  $S_2$  are the amplitudes of the moon and sun's semi-diurnal harmonic constituents respectively, and  $Z_0$  is MSL (Doodson & Warburg, 1941; Pugh, 1987).

Sea level changes on seasonal and inter-annual timescales are important to the upper limit of coral growth. They need careful identification in tide gauge data and their fluctuations over relatively short periods can be misinterpreted as local rates of sea level rise. For example, in regions of the western Pacific Ocean (within latitudes  $\pm 15^\circ$ ), sea levels dropped by around 30 cm yr during the 1997–8 major El Niño (*El Niño*, *La Niña*, and *ENSO*) and the following year, coming out of *El Niño*, the sea level rose by around 30 cm (Church, et al., 2006). MSL in many tropical regions affected by monsoons has significant seasonal variation; for example, MSL in the *Red Sea And Gulf Of Aqaba* changes 0.5 m between winter and summer monsoons (Admiralty Tide Tables).

Wave heights over reefs will influence the type of dominant coral species with hardy types more resistant to the *Reef Front Wave Energy*. The maximum wave height on a *reef flats* is dependent on water depth and, therefore, on tide level and *Wave Set-Up*, where maximum wave height on a horizontal reef flat is 0.4 (reef flat water depth, see *Reef Flats*) (Sheppard, et al., 2005).

### Coral desiccation and solar insolation

The local time of extreme spring low water is critical to the upper growth of coral reefs i.e., when and how long they are exposed to air and direct UV sunlight, leading to potential desiccation of corals. Corals exposed to air and direct sun for longer than 3 hours, start to wilt and expel the zooxanthella symbiotic algae (Hopley, 1986).

Lowest spring tides occur, when the moon's ( $M_2$ ) and sun's ( $S_2$ ) semidiurnal tides are in phase. As the sun's semi diurnal tide constituent ( $S_2$ ) is fixed to the solar day, so the lowest springs always occur at the same time each day for a location when this  $S_2$  phase is at 180 degrees in the local time (Pugh & Rayner, 1981; Pugh, 1987; Guilcher, 1988).

Time of high water spring tides occurs at  $G * 2$  minutes past midday or midnight (GMT or UT), where  $G$  is the Greenwich phase lag of the  $S_2$  constituent. The low spring tides occur 6 hours before or after this high water time. Phase lag  $G$  can be obtained from harmonic analysis of observed tidal data. GMT can easily be converted to the local time zone. If phase lags 'g' are used in the local time zone, as listed in Admiralty Tide Tables, the same method of determining spring HW and therefore LW is obtained using  $g * 2$ .

Conversion to phase lag  $G$  in GMT/UT from the local time zone phase  $g$  is obtained using  $G = g + \text{zone shift in hours}[\text{west, positive}] \times \sigma$ , where  $t$  is the time zone difference in hours and  $\sigma$  is the angular speed of the relevant constituent (30 degrees per hour for  $S_2$ ) (Pugh, 1987).

For example at Aldabra Atoll, Indian Ocean (*Indian Ocean Reefs*) with time zone GMT + 0300, the oceanic

phase lag  $G$  for  $S_2$  is  $63^\circ$  and  $g$  is  $153^\circ$ . High water springs coincide with  $G * 2 = 126$  minutes past midnight or midday at 14:06 and 02:06 and lowest water springs occurs at 08:06 and 20:06 GMT or 11:06 and 23:06 local zone time.

The Great Barrier Reef exhibits abundant reef flat coral development with lowest spring tides occurring at 14:16 pm at Cairns ( $g$  for  $S_2 = 248^\circ$ ) and 14:38 pm at Heron Island ( $g$  for  $S_2 = 259^\circ$ ). The adjacent Coral Sea reefs have similar times of lowest spring tide.

The tropical seas around Sumatra and Java are dominated by diurnal tides where low tide exposure time for corals is extreme. The dominant  $K_1$  principal solar diurnal harmonic has an angular speed of 15.0411 degrees per hour, so the extreme lowest tides will not occur at the same time of day/night as  $K_1$  advances 4 minutes in 24 hrs.

Tidal predictions, harmonic amplitudes and phase lags are published in most nationally produced tide tables (i.e., NOAA NOS, ANTT-Australia, UKHO). Cotidal charts are useful in visualizing the phase and amplitudes of diurnal or semi diurnal tides in oceans and shelf seas but are difficult to produce in complex coastal waters. The phases of the  $S_2$  harmonic on the cotidal charts are particularly useful in determining the exposure times of corals. For ease of computation and comparison of adjacent seas and time zones the use of phase lag  $G$  in GMT/UT is the convention.

### Diurnal and semi diurnal tides

The distinction between local diurnal and semi diurnal tidal regimes is important in assessment of coral growth, exposure times and desiccation. Diurnal tides dominate in parts of the tropical seas such as around Sumatra, Java and Papua New Guinea. This will significantly prolong exposure times/desiccation of reefs during low water and influence the limit of the upward growth of corals.

The form factor  $F$  (Pugh, 1987; Pugh, 2004) indicates whether local tides are diurnal or semi diurnal and is determined from the ratio of the principle diurnal and semi diurnal harmonic constituent amplitudes, where;

$F = (H_{K1} + H_{O1}) / (H_{M2} + H_{S2})$  and if;  
 $F = 0$  to 0.25 semidiurnal tides dominate,  
 $F = 0.25$  to 1.50 mixed mainly semi diurnal  
 $F = 1.50$  to 3.00 mixed, mainly diurnal  
 $F > 3.00$  diurnal tides dominate.

### Atoll lagoon tidal flushing & residence time

Tidal flows in atoll lagoons (*Lagoons*) are also important in exchanges of water in and out of the narrow entrances.

The twice daily tidal flushing of enriched nutrients (*Nutrient Pollution/Eutrophication*) and organic particulates out of a lagoon benefits nearby outer lagoon corals and fish productivity often seen as oceanic fish shoals feeding at lagoon entrances on ebb tides. The less dense buoyant plume of lagoon water on the ebb tide will feed outer atoll corals/fish in the advection-dispersion mixing process or wind induced longshore current frontal system that can form along the edge of the *atoll* (Wolanski & Hamner, 1988).

The tidal flood of cooler oceanic water helps regulate the temperature and salinity balance in the atoll lagoons which would otherwise increase due to evaporation and solar radiation. Likewise the tidal inflow of oceanic waters avoids eutrophication in the *Lagoons* which would be harmful to lagoon corals and fish.

In atoll lagoons with only narrow entrances such as Diego Garcia and Aldabra (*Indian Ocean Reefs*), tide ranges are reduced and the times of high and low waters are delayed (phase lag) on the oceanic tides (Kjerfve & Knoppers, 1991), which has implications for reef flat upper growth and exposure times.

The practical ratio of minimum inlet(s) channel cross sectional area(s) to the volume of tidal prism within *lagoons* or bays is empirically established as 0.0656 (tidal prism) (Pugh, 2004). If the inlet is narrow or constricted by sand banks, the tidal flow is restricted and the lagoon does not flush, eutrophication occurs with accumulated *nutrients* along with problems of excessive solar heating, leading to mortality of corals.

*Residence Time* for a lagoon can be approximated by (Lagoon depth/Tide range)  $\times$  tidal period (Pugh & Rayner, 1981). The lagoon of Aldabra Atoll, with approximate values for surface area of  $204 \times 10^6 \text{ m}^2$ , volume  $800 \times 10^6 \text{ m}^3$  and depth 4m, has mean spring tide range of 2.78m, (i.e.,  $2(M_2 + S_2)$ ) and neap range of 0.94 m (i.e.,  $2(M_2 - S_2)$ ). This results in residence times of 18 hours (springs) and 53 hours (neaps) for complete lagoon water tidal exchange for a tidal period of 12.42 hours ( $M_2$ ). These times are comparable to Cocos Atoll, Indian Ocean (*Cocos (Keeling) Islands*) (Kench, 1998).

The tide, ebb and flood through lagoon shallow inlets produce plumes of coral sand deposits (Guilcher, 1988) forming sand banks and alluvial fans.

### Tidal distribution of coral eggs/planula

During the annual coral spawning event the fertilized eggs are dispersed by the tides and winds but soon form long surface patches that do not disperse as for normal advection-dispersion in which the width of the patch would normally increase with time (Wolanski & Sarsenski, 1997). During the larvae planula stage of development they are dispersed to the upper surface water column. The residual tidal current vector (difference between ebb and flood) will influence further advection-dispersion (tidal current ellipses have symmetry if ebb and flood vectors equate, otherwise they can be asymmetric and accumulate a residual tidal component over several tidal cycles).

### Tidal stirring/island wakes

Tidal currents can create eddies and wakes in the lee of atolls and reef islands (Wolanski, 1994). Eddies and wakes may only occur during peak tidal currents and only on certain islands/atolls. The turbulence helps in vertical and horizontal mixing of *nutrients*, plankton and temperature from lower stratified layers and benefits to corals.

### Tidal jets

If a series of reefs form a barrier to tidal flows then *Tidal Jets* can form between the reefs. Such an example is seen, along the Ribbon Reef (*Barrier Reef (Ribbon Reef)*) complex off Northern Australia's Great Barrier Reef (*Great Barrier Reef: Origin, Evolution, and Modern Development*). Wolanski, et al. (1988), observed mushroom shaped vortex pair jets on the flood tide helping to sustain the inshore *Halimeda* banks with nutrients. The *nutrients* are upwelled in the strong tidal currents from the lower mixed layer on the outer deeper continental shelf waters. On the flood tide the adjacent corals do not benefit from the nutrient enriched tidal jet. However, on the ebb tide the offshore jet entraps the upwelled nutrients and has benefits for offshore reefs.

### Tidal shelf fronts

The formation of shelf sea fronts (Simpson, 1998) between regions of buoyant stratified water and tidally mixed water has importance in the vertical circulation of *nutrients* from below the pycnocline/thermocline. Simpson and Hunter (1974) developed the relationship between depth ( $h$ ) and tidal velocity ( $u$ ), where if  $\log_{10} (h/u^3) \approx <2$  then mixing by tidal currents will overcome buoyancy. Such large scale fronts do not occur on the Great Barrier Reef but may have significance in other coral populated regions, however limited research is published mostly linked to fisheries. Areas of strong tidal dissipation that can overcome buoyant stratification occur in coral abundant regions in the Andaman Sea, Western Australia (*Western Australian Reefs*) and Sunday Islands, Gulf of Panama, Malacca Strait, Mindanao to N. Guinea and Oman (Hunter and Sharp, 1983). Recent measurements of tidal dissipation by satellite altimetry confirm such regions (Egbert & Ray, 2000).

### Tidal mixing and coral bleaching

Tidal currents in the vicinity of coral reefs are an important source of mixing during periods that lead to Coral Bleaching. These periods are characterised by high insolation, low wind and swell and are known as doldrums in the tropics, when a surface warm layer forms that can cause corals to become heat stressed and expel their symbiotic algae leaving them to look "bleached". The only potential source of cooler waters are from below this layer and mixing by tides can be the critical process that can break down this stable surface layer and spreading the heat throughout the entire water column.

Simpson and Hunter (1974) provide the criterion that can determine whether tidal mixing is strong enough to generate turbulence from the sea floor to reach the surface. Skirving and Steinberg (2003) applied this method utilising a tidal model of the Great Barrier Reef (GBR) by Bode et al. (1997) to generate a mixing map. It also helps explain the complex SST patterns found along the GBR reef matrix and Queensland shelf. A series of studies have been made to determine the applicability to other reef

types such as Scott Reef in the Timor Sea (Bird, 2005) and Palau (Skirving et al., 2010).

The Great Barrier Reef Ocean Observing System (GBROOS) observes these mixing processes in near real time by ocean surface radar and an array of moorings monitoring the stratification and mixing events in the water column (DiMassa et al., 2010).

### Tides in resonance

In bays and long inlets the tide can be in resonance or co-oscillation with the external oceanic or shelf tides, influencing significant changes in tidal range and phase (Bowden, 1983).

An example in tropical coral seas is the *Red Sea And Gulf Of Aqaba*, which exhibits a fundamental co-oscillation with the external tide of the Gulf of Aden. The tide is formed by opposite flows of coastal trapped Kelvin waves which oscillate about the central amphidromic point. The central node or amphidromic point in the middle of the Red Sea between Jeddah and Port Sudan experiences minimal tide and the extreme north and south are in opposite phase in high and low tides (Pugh, 1987).

Spring tidal ranges in the north at Quseir are 0.54 m and south at Gizzan are 0.82 m and middle at Jeddah 0.16 m (from  $2(M_2 + S_2)$ ), but a seasonal MSL variation of 0.5 m dominates with a low in summer and high in winter. Therefore, reef flats may be permanently exposed in the hot summer months in the central region with minimal semi-diurnal tides. At Jeddah, the reef flats are poorly developed for these reasons along with the  $S_2$  tidal phase producing low water springs at 14.30 (Local Time) near the diurnal peak in ambient air temperatures. Hence exposed coral desiccation is extreme in such conditions.

### Internal tides & waves

Internal tides or waves can form on density boundaries in the ocean (e.g. pycnocline) or on the thermocline in oceanic waters and halocline in coastal waters. If their frequency is the same as the surface astronomical tides (barotropic tides), then they are referred to as Internal Tides or Baroclinic Tides when vertical density differences are involved.

Internal waves can also occur at non tidal frequencies. They can all feature wave breaking, internal surf and very large amplitudes, which can influence vertical mixing with implications for coral reefs normally situated in oligotrophic, nutrient low oceanic water. Internal waves can also occur where there is continuous vertical density stratification that is not confined to a simple two layer situation. Here internal waves can travel in all directions and be reflected/refracted off sea bed and shelf, transferring energy throughout.

The principles of internal waves and tides are discussed by Pond and Pickard (1986) and Wolanski, (1994), with a more in depth mathematical approach dealt with by Vlasenko et al. (2005).

Internal waves can be created when the oceanic surface tide wave (barotropic surface tide) passes over an ocean

shelf or around a coral atoll or shallower obstruction such as a seamount. It is then split into a less energetic surface wave and other internal modes with different wavelengths and propagation speeds. This cascading process, from the barotropic surface tides to the baroclinic components, leads to the transformation of tidal energy into turbulence and heat, an important process for the dynamics of the lower ocean (Vlasenko, et al, 2005).

Wolanski and Deleersnijder (1998) and Wolanski et al. (2004) investigated the formation of internal tides/waves around reefs and islands off Western Australia at Scott Reef and at Palau, Micronesia respectively. At Scott reef, strong macro-tidal currents of  $0.6 \text{ ms}^{-1}$  formed internal waves of 60 m peak to trough at diurnal, semi diurnal and higher frequencies.

At Palau, local mixed semi-diurnal surface tides were typically 2 m in amplitude and during spring tides the internal waves exhibited amplitudes of 50–100 m and peaked at 270 m at a range of frequencies including diurnal and semi-diurnal. The implications of such large amplitude internal waves on corals in the region 60–120 m was the rapid temperature change (*Temperature Change: Bleaching*) which was recorded as 8–10°C in an hour and up to 20°C in 30 minutes. The rapid temperature change may stress corals and limit the lower depth of less tolerant species.

From the Scot Reef experiment, observations and modeling results indicate that the 60 m internal waves (peak to trough) cause significant variation in the currents and temperature change in the upper 200 m helping to bring nutrients from below the pycnocline (at 100 m) to 40 m of the surface. Of importance to corals, these nutrient rich waters are then dispersed amongst the spur and grove (*Spurs and Grooves*) structures and surface as observed at the Grand Cayman, Caribbean (Roberts, et al, 1977).

Wang, et al, (2008) used ADCP, CTD and current meters to observe internal waves off Taiwan and clearly describes the vertical profiles of orbital internal tidal ellipses and current vectors, associated with internal waves. The amplitudes of internal wave isotherm displacement observed at over 200 m will influence nutrient mixing and temperature stress on corals.

Katsumata, (2006) observed and modeled internal tides/waves on the Australian North West Shelf, where the energy dissipation of strong tidal currents produce significant vertical stirring and mixing, important for vertical pumping of nutrients.

Energy dissipation occurs when the kinetic and potential energies of a water mass is transformed into other features such as internal waves, eddies, gyres through turbulence and vertical shears encountered with frictional boundaries such as reefs, atolls and sea bed. Significant tidal energy dissipation of the deeper oceans occurs in regions of rough bathymetry such as the *Hawaiian Ridge*, as well as shallow seas and helps in the creation of strong internal tides (Pugh, 1987; Egbert & Ray, 2000; Cartwright, 2001). Internal tides in shelf seas have benefit to coral productivity with vertical mixing of nutrients from below the pycnocline (Wolanski, 1994).

## Tide data

Nationally produced tide table publications (NOAA NOS-USA, ANTT-Australia, UKHO) provide annual tide predictions, constituent phase lags and amplitudes. On remote coral reefs/atolls, there may be limited or no information on tides or local geodetic survey bench marks and may require onsite tide observations and harmonic tidal analysis.

UNESCO's Intergovernmental Oceanographic Commission promotes research quality sea level observations through the Global Sea Level Observing System (GLOSS). Near real time tidal data are accessible from many GLOSS gauges (<http://www.gloss-sealevel.org>). MSL and delayed mode data sets, publications, training material and other resources are available from the Permanent Service for Mean Sea Level (PSMSL) of the International Council for Science (<http://www.pol.ac.uk/psmsl>).

## Summary

The influence of tides on coral reefs is not just confined to the semi-diurnal, rise and fall of sea level. Physical oceanographic studies of coral reefs have investigated the *Great Barrier Reef* where there is ready access and resources that are available for research, with significant research also on Indian Ocean and Pacific coral reefs and atolls. Future coral reef investigations may consider the accumulated literature from the Great Barrier Reef and other much-studied locations in the Pacific and Indian Ocean, with an overall understanding of the interaction of their physical and biological processes.

## TIDAL JETS

Edward Drew  
 Belgian Gardens, Townsville, QLD, Australia

### Definition

A tidal jet is a fast-moving intrusion of water issuing from a narrow gap through a physical barrier between two bodies of water. The jet is generated by the pressure resulting from height differences between the two water bodies when the surface of one is rising with the tide, but the flow through the channel is too restricted to keep the levels equal. The reverse will occur when the tide is falling.

Tidal jets can occur in coral reef regions when an extensive outer barrier reef is penetrated by only a limited number of narrow channels. Such jets have been studied in considerable detail along the 650 km tract of ribbon reefs between 11 and 16°S on the northern Great Barrier Reef.

The continental shelf lagoon in that area is 40–50 km wide and the seabed slopes to a depth of 50 m at the outer barrier. Beyond this is the Coral Sea where the continental slope immediately descends steeply, reaching 500 m within 2 km and continuing to at least 1,000 m. The outer barrier is open for only about 10% of its length (Pickard et al., 1977), presenting high resistance to the tidal flow, and causing considerable height differences between the ends of the channels, particularly during spring tides. The resulting strong tidal currents through the channels initially cause a fan-shaped jet to develop, spreading behind the adjacent reefs but, as water velocities increase, this separates completely from behind the reefs to form a distinct mushroom jet capped by rotational vortexes. This jet transports ocean water into the lagoon from beyond the barrier reefs (Figure 1a).

Water in the lagoon and that above the seasonal thermocline in the adjacent ocean, is low in essential nutrients such as nitrogen and phosphorus. However, much greater quantities of these nutrients occur below the thermocline at about 65 m depth in the Coral Sea.

The rapid inflow of water into the channels during rising spring tides can suck water from considerably deeper than the outer channel sill. This process, the Bernoulli Effect, can result in up-welling of cold, nutrient-rich water from below the thermocline. This water is then transported through the channels as a denser bottom layer (Figure 1b), effectively pumping nutrients into the outer lagoon.

Computer modeling indicates that channels 800 m wide, 40–45 m deep at the outer sill and spaced at least 4 km apart can result in significant upwelling from below the thermocline. Many of the channels through the outer barrier meet these criteria (Wolanski et al., 1988).

On the shelf, directly behind the barrier reefs, there is a sparsely colonised sandy strip a few kilometres wide.

**Tidal Jets, Figure 1** (a) Well developed tidal jet and vortex-pair system in plan view; (b and c) vertical sections through the upper continental slope and water column, passing along the axis of the channel. b = flood tide, c = ebb tide.

The seabed then frequently rises rapidly from 50 m up to 30 m depth where extensive meadows of the calcareous green alga *Halimeda* grow atop banks of *Halimeda*-rich gravel. These banks can extend up to 12 km further inshore and cover ca. 2,000 km<sup>2</sup> of seabed (<http://home.austarnet.com.au/research1/atlas/atlas.htm>).

They are situated where the tidal jets decay and deposit their nutrient-rich, up-welled water. The involvement of these nutrients in supporting rich algal growth in the otherwise nutrient-depleted shelf waters is further implied by absence of the *Halimeda* banks behind channels not satisfying the requirements for nutrient upwelling induced by tidal jets (Drew, 2001).

On falling tides, strong currents flow out through the channels, transporting nutrient-depleted water from the shelf. Similar tidal jets develop in the Coral Sea and these can also entrain nutrient-rich water from below the thermocline (Figure 1c). This may explain the considerable growth of phytoplankton visible just beyond the outer barrier on CZCS Satellite imagery.

## TROPICAL CYCLONE/HURRICANE

Terry Done  
 Australian Institute of Marine Science, Townsville MC,  
 Australia

## Definition

Tropical cyclone is a generic term that also includes hurricane and typhoon. Meteorologists define a tropical cyclone as "... a non-frontal low pressure system of synoptic scale developing over warm waters having organized convection and a maximum mean wind speed of 34 knots (70 km h<sup>-1</sup>) or greater extending more than half-way around near the center and persisting for at least 6 h" (BOM, 2009).

In the Northern Hemisphere, tropical cyclones rotate in an anticlockwise direction. They are referred to as *hurricanes* (North Atlantic, North East Pacific east of the dateline), or *typhoons* (Northwest Pacific east of the dateline). In the Southern Hemisphere, they rotate in a clockwise direction, and are called *cyclones* in the Indian Ocean and the Pacific Ocean west of 160°E, and *hurricanes* east of 160°E.

Tropical cyclones have a distinctive "eye," which is usually some tens of kilometers across, and a surrounding cloud mass that is some hundreds of kilometers across. Unlike *tornadoes*, which are an order of magnitude smaller and generated on and move across land, tropical cyclones are generated only at sea.

## Introduction

Cyclones are a normal part of the marine and coastal environment in the latitudinal bands 7–25° north and south of the equator – about 70% of the tropical seas in which coral reefs occur. Affected reefs are exposed to one or more of four potential impacts: powerful short period waves generated in chaotic seas generated by winds spiralling in toward the eye; swells (high, long period waves) that break onto reefs at great distances from the eye; storm-surges (elevated sea levels – a direct consequence of the low-pressure cell), and flooding rains (either directly or in river plumes).

In a major review, Scoffin (1993) listed the following reef areas as regularly exposed to cyclone impacts: north-west Pacific Ocean from the Marshalls and Marianas to the Caroline Islands, South China Sea, and the Philippines; southwest Pacific Ocean from Society, Cook, and Samoan Islands, Tuvalu, to Fiji, Vanuatu, New Caledonia, and the Great Barrier Reef of Australia; the north Indian Ocean, including the Andaman Islands, Sri Lanka, and the Lakshwadeep islands; south Indian Ocean, Cocos Keeling, Chagos Archipelago, and the islands between Madagascar and the Mascarenes; the northwest Atlantic Ocean including the Gulf of Mexico and the Caribbean Sea.

By contrast, equatorial reefs (to latitudes ~7° north and south) – notably including most of those in the Coral Triangle (see entry *East Indies Triangle of Biodiversity*) – are rarely if ever exposed to such extreme environmental impacts as those generated by cyclones. These areas are the Maldives; the East African coast; the Red Sea; the area from the Malaysian peninsula through northern Indonesia, Papua New Guinea, and the Solomon Islands; the Pacific atolls of Kiribati, the Phoenix group, many of the Line Islands, and the easternmost Tuamotus (Scoffin, 1993).

## Cyclone genesis

Cyclones are generated and maintained over the ocean by a combination of meteorological and oceanographic conditions and processes that rarely occur nearer than 500 km from the equator: a “heat engine” (warm waters ( $\geq 26.5^\circ\text{C}$ ) to ~50 m depth or more); a cool, moist atmosphere with weak vertical wind gradients that draws heat from the ocean heat engine to generate thunder storms; sufficient Coriolis forces to maintain the low-pressure cell; a pre-existing weakly organized rotating weather system (BOM, 2009). Such conditions occur every summer, generating cyclones that move across the ocean at speeds of 10–25 km h<sup>-1</sup>. The average wind speed at 30–50 km radius around the eye’s center ranges from 62 to 244 km h<sup>-1</sup> (gusting to 88–344 km h<sup>-1</sup>, Table 1), creating destructive waves as highly turbulent wind energy is transmitted to the water surface. The net movement of these wind waves is in the direction of the wind flow (Massel, 1999). Since a cyclone’s wind flow is rotating, it can drive powerful waves into parts of reefs that are normally highly sheltered from the prevailing fair weather waves and whose corals and reef matrix are ill-adapted to withstand strong wave action. When the eye is in motion, wind speeds and waves are larger on one side of the track than the other (as the forward motion is added or subtracted to the rotational speed). There is, for example, a 50-km h<sup>-1</sup> difference in wind speed to the left and right of the track of a cyclone moving at 25 km h<sup>-1</sup>, with concomitant differences in the waves they generate.

## Waves and currents

Hearn (1999) and Massel (1999) provide general accounts of waves in coral reef environments. As a wave approaches

**Tropical Cyclone/Hurricane, Table 1** Comparison of the USA hurricane scale with the Australia’s tropical cyclone categories. The demarcation points are not precise – this table is intended to provide a rough comparison only. ([http://www.bom.gov.au/weather/wa/cyclone/about/faq/faq\\_def\\_2.shtml](http://www.bom.gov.au/weather/wa/cyclone/about/faq/faq_def_2.shtml))

a gently sloping reef, it accelerates across the reef slope and breaks on its shallows. Compared to normal fair-weather waves, a cyclone-generated wave introduces strong hydraulic conditions into reef zones and habitats usually exposed to more moderate forces. Bigger than normal waves, especially if coincident with a low tide, introduce strong water motion deeper down the slope than its normal fair-weather depth. A storm surge, especially on top of a high tide, causes the breaker zone to move toward the back reef, relative to its normal fair-weather position. In each case, the anomalously high forces impact upon reef components (corals; framework) that developed in calmer conditions and are structurally ill-adapted to the extreme high forces. Beneath the wave's surface expression, the upward component of oscillatory water motion exerts lift forces on the underside of horizontal projections from the reef (corals; framework), horizontal components undercut them, and the downward component exerts percussive impacts.

### Hindcasting winds, waves, and coral damage

Cyclones routinely travel for hundreds to thousands of kilometers at 10–25 km h<sup>-1</sup>, sometimes pausing along the way. Kjverfve et al. (1986) provided functions to hindcast the progressive changes in local wind speed and wave characteristics (significant wave height; period) at a single reef site (Discovery Bay, Jamaica) as a hurricane passed 50 km to its north. Done (1992) applied an extension of this approach to estimate local wind speeds, duration, and direction of attack as a proxy for wave impact and predictor of damage at a large number of sites at varying distances (0–160 km) from the path of a cyclone that crossed the Great Barrier Reef, Australia. Massel and Done (1993) and Madin and Connelly (2006) quantified the relationship between wave energy and the breakage or dislodgement of coral of different sizes, shape, and tenacity of attachment. Massel and Done (1993) produced survivorship curves for unattached head corals at different locations and depths on a reef, factoring in the attenuation of wave energy with depth, coral growth rates, and the meteorological record of cyclone frequency and intensity.

### Cyclone effects on coral reefs

The repetition of short-period wave impacts hundreds to thousands of times over periods of several hours causes major coral mortality and structural damage to reefs. (By contrast, any single tsunami's damaging affects are due to the actions of a very small number of extremely powerful waves – see entry *Tsunami*). Impacts on the reef include not only the direct effects of wave damage (e.g., coral breakage and dislodgement; horizontal movement of debris; Done, 1992; Scoffin, 1993; Fabricius et al., 2008), but also burial and breakage cause by the avalanche of reef and coral debris down reef slopes (Harmelin-Vivien and Laboute, 1986). While cyclone damage to corals is indisputable, Massel and Done (1993) and Madin and Connelly (2006) concluded that the damage is not caused by wave forces *per se*. These are insufficient to break

massive or branching corals which are securely attached to solid reef platform. However, the point of attachment is frequently insecure, and the object to which it is attached is often not solid reef platform (e.g., fragile and eroded framework, coral skeletons, coral rubble, or mollusc shells). Such corals can be swept, rolled, and pushed across the reef, damaging or destroying them and other corals and topographic high-spots with which they collide.

Recurrent attack by strong breaking and surging waves can undercut shallow reef framework and cause it to collapse; it can fracture and disintegrate slabs of reef framework meters across and >100 tons in weight, throwing them intact onto the adjacent reef flat (Scheffers and Scheffers, 2006). Over a period of hours, surging reef top currents move such boulders tens to hundreds of meters by overturning (rolling) and sliding (skidding) (Scheffers and Scheffers 2006; Goto et al. 2009). The latter authors estimated the characteristics of the cyclonic waves necessary to put massive reef blocks in observed reef-flat positions: at 30 m from the reef edge, a significant wave height of 4.2 m and current velocity of 6.5 m s<sup>-1</sup>; at 260 m from the edge, 1.5 m and 3.1 m s<sup>-1</sup>. These are extraordinarily large waves and strong currents compared to fair-weather conditions, wherein values one-third of these would be normal for equivalent places. In some settings open to long ocean fetches, the initial upward displacement of rubble beds and very large coral heads or reef blocks may have been made by a tsunami (Nott 1997; Scheffers and Scheffers, 2006; see also entry *Tsunami*).

Cyclonic waves can set up extraordinarily strong currents across a reef flat. Working in concert with existing geostrophic and tidal currents, jets, and eddies, these currents move sand, shingle, and small debris *en masse* into new reef flat or onshore positions, the final location depending in part on the sea level relative to the reef top (Hearn, 1999) and the state of the tide during the cyclone's passage (Scoffin, 1993). Extreme storms create, move, or destroy sand or shingle cays (Scoffin, 1993) and deposit what soon becomes discrete habitat with distinctive biota (e.g., reef-flat boulder zones and shingle beaches, both of which are derived from broken and dislodged corals). Gravel, rubble, blocks, and corals are propelled through the water, rolled, and skidded across the reef to lower energy deposition sites, be they talus beds at the base of reef slopes, reef-flat boulder ramparts, sheltered back-reef lagoons, or the slopes or floors of channels through or between reefs. In transit, entrained rubble and corals smash against other corals, causing breakage and injury to both entrained and attached corals (Done, 1992; Scheffers and Scheffers, 2006). Wholesale movement of thousands of tons of sand, gravel, and rubble can eliminate or shift an entire sand cay, bury thriving coral assemblages, expose formerly buried substrata, raise the height of the intertidal reef flat, add to an adjacent shoreline, and modify reef-top draining, as channels are opened up and occluded. On the reef flat during the actual passage of the cyclone, as Scoffin (1993) suggests, processes of deposition will predominate during low tide, and the

processes of erosion during high tide. The final geological signature of a particular event at a particular reef may thus be greatly influenced by the state of the tide at the time cyclonic conditions subsided.

### After the cyclone

In the weeks to decades that follow a serious impact, changed reef-top hydrodynamics may be to the benefit of coral-dominated ecological assemblages (deeper and better flushed areas more accessible to colonizing organisms), or to their detriment (when loss of circulation causes deleterious changes in temperature, salinity, oxygenation, and turbidity – Macintyre, 2007). The freshly dead skeletons, rubble, and denuded framework in previously coral-dominated areas will be colonized by a succession of microbes, cyanobacteria, and algae. In poorly flushed areas, this benthic shift may be at the expense of any potential coral recolonization; in well flushed areas, it may be a step in a succession to encrusting coralline algae and eventual dominance by corals. In the latter circumstances, periodic disturbance can help maintain coral and coral-dependent species diversity in the long term (Connell, 1978; Bythell et al., 2000; Woodley, 1992; Done et al., 2007).

### Contrasting perspectives on tropical cyclones

From an ecological perspective, the damage to a particular part of a reef (breakage, dislodgement and death of coral colonies) may be minor (requiring only months to years for coral populations and dependent biodiversity to recover) to catastrophic (years to decades). Indeed, by transporting viable coral fragments, a storm can initiate the re-population of previously barren areas, newly devastated areas that the storm itself created, or previously buried substratum that the cyclone exposed. From a geological perspective, the generation of new sediments (coral breakage) or the movement of existing deposits caused by a single cyclone may represent anything from a minor blip to a major transformation of the reef that will be preserved in its structure for millennia (Scoffin 1993; Scheffers et al., 2009). Though a given cyclone may be highly damaging to corals and reef framework, in some settings, the coral regeneration, amalgamation, and infilling initiated by the event can cause reefs to extend laterally by “stepping out over their own debris” (Blanchon and Jones, 1997).

At a regional scale, the historical cyclone regime (the frequency and extent to which coral populations are decimated, incipient reef structures are smashed, inundated by flood waters, or smothered in silt) may also be reflected in both ecology and geology. Ecologically, the specific regime can affect the rate of population turnover and the size structures of important reef building corals (Done, 1992; Massel and Done, 1993; Madin and Connelly, 2006); geologically, it can determine the ability of reef growth to “keep up” during periods of rapid sea-level rise and horizontal transgression of the sea across coastal lands (Macintyre, 2007; Larcombe and Carter, 2004). Indeed, the latter authors explain the absence of reefs

from large parts of the central Great Barrier Reef that were first inundated ~7 ky BP in these terms.

Systematic variation in the extent of development of buttresses and the types of dominant corals around very large reefs can be largely understood in terms of differences in the relative importance of hurricane impacts. These in turn depend to a great extent on the length of open ocean (*fetch*) to seaward of the section of reef in question. At Grand Cayman, for example, differences in buttress development are explained in terms of differences in the fetch and, thus, in the importance of hurricane-induced pruning of branching corals and the flushing of sand through canyons by return flows (Blanchon and Jones, 1997).

### Summary

Cyclones often leave broad swathes of damage to coral reefs, with significant ecological and geological outcomes. The rotating structure of any single cyclone can cause structural damage and sediment transport in areas that are normally sheltered, initiating a period of ecological regeneration within physical and environmental settings that may be quite different from those present before the storm.

Considered in the context of the Holocene period of transgression and reef development, a local cyclone regime that is too severe (in terms of frequency, intensity) may exclude coral reefs from some areas. Where the regime is more moderate, cyclones can be formative events in terms of both ecology (initiating a period of regeneration) and geomorphology (building islands; transforming reef-top morphology; facilitating lateral reef extension onto the adjacent shallow sea floor). With twenty-first century climate change, projected reduction in the reef-building performance of corals and increased severity and/or frequency of cyclone impacts have implications that are potentially important but as yet poorly understood (see entry *Climate Change: Increasing Storm Activity*).

## TSUNAMI

Paul Kench  
 The University of Auckland, Auckland, New Zealand

## Definition

*Tsunami* refers to a fast moving wave or series of waves caused by rapid displacement of a large volume of ocean water. These gravitational oscillations of the entire water body of an ocean basin possess large wave lengths (~300 km), long periods (typically 10 min to hours), and travel at great speeds across ocean basins (~220 m s<sup>-1</sup>).

## Introduction

The term tsunami is derived from the Japanese language, and literally translated it means “harbor” (*tsu*), “wave” (*ami*). More than 195 tsunami have been recorded along the Japanese coast. Despite the limited spatial extent of waves implied by this name, the term has been adopted in the scientific literature to describe the fast moving trans-oceanic wave events that have the potential to cause mass devastation.

On human timescales, devastating tsunami are a relatively rare occurrence, but the consequences of exposure to such events can be immense. Over the past century, more than 1,040 tsunami have been recorded (Scheffers and Kellett, 2003). However, the majority of these events have been low in magnitude with negligible impacts. Disastrous events, with flow depths at the coast of >10 m, constitute only about 2% of the centennial tsunami record.

On a geological timescale, tsunami are regular occurrences. Global tsunami catalogs indicate there have been more than 2,000 tsunami events during the past 4,000 years (NGDC, 2009), although this value is likely an underestimate due to the lack of early records. Coral reefs and reef-associated sedimentary landforms occur throughout the Caribbean Sea and tropical Indian and Pacific Oceans. These reef systems are surrounded by tsunamigenic seismic zones and have been subjected to multiple tsunami during the Holocene. Indeed, these ocean basins account for 75% of all tsunami. While much attention has focused on the role of extreme storms and cyclones in promoting change in coral reef ecosystems (Woodley et al., 1981; Connell et al., 1997; Done, 1992a, b; Woodley, 1992) and geomorphic structure of reef systems (Stoddart, 1963; Maragos et al., 1973; Bayliss-Smith, 1988; Scoffin, 1993; Blanchon et al., 1997), until recently little was known of the direct impact and long-term consequences of tsunami on coral reef ecosystems and associated reef landforms.

The Sumatran tsunami in 2004 was the worst tsunami disaster in recorded history. This event provided a significant impetus for research on the impacts of tsunami on ecosystems, landforms, and human communities. Of note, the event provided the first mega-tsunami with which scientists could document impacts on coral reefs, and against which they could calibrate historical reconstructions of tsunami impact.

The focus of this entry is to examine the causes and characteristics of tsunami, their interaction with reef structures and their ecological, geological, and geomorphic impacts on coral reef systems.

## Mechanisms of tsunami generation

When a major Chilean earthquake generated a Pacific-wide tsunami in 1964, little was known of the mechanisms controlling tsunami generation (Satake et al., 2007). However, subsequent scientific breakthroughs in plate tectonic theory, coupled with development of numerical models and seismic monitoring, have considerably increased scientific understanding.

Earthquakes are the most common cause of tsunami. They can cause faulting and deformation of the ocean floor that displaces large volumes of ocean water that trigger tsunami waves. Tsunami genesis is thus dependent on the location and magnitude of the seismic event and the extent of displacement of the sea bed. Earthquake sources are located deep beneath the earth surface, and since their coupling with the ocean is weak, small earthquakes generally do not generate tsunami of any consequence. It is the larger earthquakes (moment magnitude  $>8.7$ ) that generate the largest tsunami waves (Okal, 2009).

Submarine mass failure (underwater slides or slumps) or aerial landslides (sometimes triggered by lesser earthquakes) can also trigger tsunami. For example, the tsunami that impacted the northern shoreline of Papua New Guinea in 1998 resulted from a submarine mass failure triggered by a magnitude 7.1 earthquake along the boundary of the Australian and Pacific plates (Synolakis et al., 2002). Similar earthquake-triggered submarine failures have been implicated in generation of a tsunami in 1992 at Flores, Indonesia (Imamura et al., 1995), and one that inundated Hilo, Hawaii in 1946, following an earthquake near the Aleutian Islands, Alaska.

There are also non-earthquake triggers for tsunami, notably volcanoes and bolides. Large-scale volcanic eruptions in the marine environment that have generated tsunami in recent history include those of Krakatau (AD 1883) and Santorini (1630 BC). Ocean bolide impacts, while infrequent in the geological record, have the potential to generate massive tsunami, as has been inferred in the Yucatan 65 million years ago (Bryant, 2008).

Tsunami are generally categorized based on the geographic reach of their influence relative to their point of origin. Commonly, locations in close proximity to the seismic source (within 1,000 km) are considered to be in the “near-field.” Sites beyond this threshold are considered to be in the “far-field.” However, Titov et al. (2005) challenged this distinction based on the global reach of the Indian Ocean tsunami suggesting that all coastlines in the Indian Ocean basin were in the “near-field.”

### Characteristics of tsunami waves

Tsunami are characterized by wave lengths up to and in excess of 300 km, long wave periods of 10–60 min and propagation speeds up to  $800 \text{ km h}^{-1}$ . In the deep ocean, tsunami waves typically have low amplitude ( $<1 \text{ m}$ ). These parameters are in marked contrast to those of wind-generated waves, which are characterized by shorter wave lengths (typically  $\leq 0.2 \text{ km}$ ), shorter periods (3–30 s), slower propagation speeds ( $54 \text{ km h}^{-1}$ ), and greater wave heights (up to  $\sim 12 \text{ m}$ ). Another critical difference between tsunami and wind-generated waves is the location of energy within the wave, and how it is conveyed across the ocean. Wind-generated wave energy is transferred across the ocean surface, and there is no translatory flow of water until the wave comes close to the break point. The energy in the wave is mostly contained

near the surface, decaying exponentially to a negligible level by a depth of one half the wave length. In contrast, tsunami waves are much longer and energy is distributed throughout the entire water column. Moreover, there is substantial horizontal movement of the water body itself across the ocean (Yeh et al., 1994).

The generation mechanism of tsunami waves controls both their local character and their geographic reach. Earthquakes can move extremely large volumes of water as a consequence of the significant length of rupture zones ( $\sim 10^3 \text{ km}$ ), although the water column is moved vertically by only a small distance ( $\sim 10^0\text{--}10^1 \text{ m}$  in the largest quakes). For example, the Sumatran tsunami of 26 December 2004 was generated by a fault rupture that extended 1,200 km with sea floor displacement of approximately 20 m (Stein and Okal, 2005). This produced very long waves that possessed large amounts of energy and that were transmitted large distances with minimal energy loss (e.g., Figure 1). Non-earthquake sources (e.g., submarine failure), by contrast, typically displace water across a smaller linear distance ( $\sim 10^1\text{--}10^2 \text{ km}$ ) and move smaller volumes of water. The resulting tsunami waves have shorter wave lengths and undergo more efficient dispersion, losing energy during propagation, and have more limited geographic reach (Synolakis et al., 2002).

Tsunami events commonly comprise a series of large waves at intervals up to 60 min. For example, tide gauges from the eastern and central Indian Ocean show a number of large waves following the Sumatran earthquake with water-level oscillations continuing for more than 24 h (Figure 2).

### Tsunami wave propagation

Tsunami wave height, directionality, and propagation patterns are controlled by the orientation and intensity of seismic line sources and trapping by mid-ocean ridges (Titov et al. 2005). Ocean ridges guide the direction of wave propagation (Figure 1). Consequently, ocean bathymetry has a significant control on tsunami propagation behavior.

Although the height of tsunami waves in the open ocean is generally small ( $<5 \text{ m}$ ), they can shoal markedly close to the coast and produce wave run-up depths on the order of 10–100 m (Bryant, 2008; NGDC, 2009). As waves enter shallow water they are transformed, reducing in speed and increasing in height. The degree of shoaling and final interaction of tsunami waves with reefs and shorelines is dependent on the nearshore bathymetry and planform shape of reefs. In general, shoaling is most efficient and produces largest wave heights on low gradient and shallow coastal shelves (Okal, 2009). Spatial differences in bathymetry, therefore, is one of the major controls on the transformation of tsunami waves and their consequent impacts on coral reefs and reef-associated landforms (Ioualalen et al., 2007; Scheffers et al., 2009). For example, while the mid-ocean height of the Sumatran tsunami was mostly  $<0.7 \text{ m}$ , maximum wave height, near the coast at Banda Aceh was estimated at 10–15 m (Spencer, 2007).

**Tsunami, Figure 1** Global reach of the December 2004 Sumatra tsunami. Colors show maximum computed tsunami heights during 44 h of wave propagation simulation. Contours show computed arrival time of tsunami waves. Circles denote the locations and amplitudes of tsunami waves in three range categories for selected tide-gauge stations (From Titov et al., 2005).

### Interaction of tsunami with coral reefs

The interaction between tsunami waves and coral reefs occurs at a number of spatial scales. The nature of these interactions influences tsunami wave propagation, the specific transformation of tsunami waves, and the way in which tsunami wave energy is released on reef structures and associated reef landforms.

#### Macro-scale influence of reef systems on transoceanic tsunami behavior

Mid-ocean archipelagos and shelf reef systems (barrier reef complexes) present a physical barrier to tsunami waves, modifying their transoceanic propagation in a number of ways. First, the interaction absorbs energy from tsunami. For instance, during the Sumatran tsunami, the tsunami's interaction with the Laccadive – Maldives – Chagos ridge and atoll system reduced its height by as much as 0.3 m (Figure 1). Second, it can deflect tsunami energy into otherwise “sheltered” coastal sites, and alter the overall direction of the tsunami's propagation. For example, reflected waves from the Maldives have been implicated in the destruction on the southwest coast of Sri Lanka (Liu et al., 2005; Kowlaik et al., 2007).

#### Reef platform – tsunami interactions

At a finer spatial resolution, a network of oceanic reefs or individual reef platforms produces a number of distinct transformations in tsunami wave characteristics that are

dependent on the planform configuration, density, and size of the reefs. Where there are extensive linear fringing or barrier reef systems that either adjoin or are close to continental coastlines or high islands, wave energy is dissipated first onto the reefs, then onto the coastline. It is in these reef settings that energy interaction with reefs is most intense and where there is the greatest potential for impacts on reef ecology and geomorphology. These interactions are discussed in more detail later.

In mid-ocean archipelagos and open networks of reef systems, the reef network acts as a semi-permeable membrane to the propagation of tsunami wave energy. Gaps between reefs induce localized refraction and diffraction patterns. The interaction of tsunami with the seabed and reef structures extracts energy from the tsunami.

Where individual roughly circular islands have dimensions comparable to the tsunami's wave length, the wave may refract completely around the island, resulting in amplified wave and run-up height on its leeward side. Such behavior was observed at Babi Island, a conical shaped island approximately 2 km in diameter, as a consequence of the 12 December 1992 earthquake-generated tsunami at Flores Island, Indonesia (Yeh et al., 1993; Minoura et al., 1997). Numerical models and laboratory experiments showed that tsunami waves would have penetrated sheltered areas of Babi with minimum loss of energy (Yeh et al., 1994). Maximum run-up height and velocity were amplified 1.7 and 3.0 times, respectively, on the leeward sides of the island, destroying two coastal villages.

**Tsunami, Figure 2** Tide gauge records of the December 2004 Sumatra tsunami in the eastern and central Indian Ocean (From Fisheries and Oceans Canada, 2005).

### Tsunami shoaling and energy dissipation on coral reefs

The type of wave shoaling varies among reefs of different structures and geographic locations. Such differences can have significant implications for the way energy is released on, or adjacent to, coral reefs and the subsequent ecological and geomorphic impacts.

Mid-ocean atolls are characterized by small dimensions, large surrounding ocean depths (in excess of 3,000 m), and very steep underwater structures (slopes reaching 40°). Consequently, atoll islands present a steep and small obstacle to tsunami propagation and present limited potential for shoaling and result in less impact (Searle, 2006; Obura and Abdulla, 2005). For example, during the Sumatran tsunami, wave heights in Maldives atolls were raised from mid-ocean heights of 0.7 m to heights of only ~2.5 m (Titov et al., 2005; Figure 2). In these circumstances the wave structure remains stable (does not break) and the wave can propagate across coral reefs and over associated reef landforms (islands and coastal plains), inundating coastal areas in the form of a progressively rising swell over distances of up to 10 km in the near field (Okal, 2009).

In contrast, where fringing and barrier reefs are located on broad and low gradient continental shelves (<10°) tsunami can shoal rapidly and break as they interact with

coral reefs and coastlines. In such instances, the waves hit the shoreline as a turbulent bore (broken wall of water) with strong flow (Heller et al., 2005). Such waves lose their energy through turbulent friction and dissipation with the sea floor, reef structure, and land surface. However, due to the high velocity of tsunami waves, turbulent bores can flow several kilometers across the land surface (Jaffe et al., 2006). These turbulent bores can be destructive to seafloor, reefs, and shoreline, and the dissipation of energy at that stage influences, to some degree, the extent and force of inland propagation of the wave.

Some authors note that coral reefs can act as effective buffers to shoreline impacts of tsunami (e.g., Kunkel et al., 2006; Cochard et al., 2008). Others (Campbell et al., 2007; Paris et al., 2009) note they are not necessarily effective at all. Positioned directly at the interface between shallow marine and terrestrial environments, coral reefs can be one of the first ecosystems to feel the effect of tsunami waves. This role in buffering the influence of tsunami has been proposed by a number of authors (Okal, 2009; Chochard et al., 2008). The surface roughness and shallow depth of reefs and reef flats is able to extract energy from waves close to the coast. Observations supporting this buffering effect have been documented in the Indian Ocean, where Mauritius (which has an encircling reef) experienced significantly less damage than Réunion Island (where the coral reef is absent from much of the shoreline; Okal, 2009). However, other studies (e.g., Campbell et al., 2007; Cochard et al., 2008) suggest that regional comparisons do not support such assertions and tsunami impacts are more locally variable.

Conspicuous aspects of the final interaction of tsunami with coral reefs and reef-associated landforms are the run-up and backwash phases of each individual wave. Run-up heights (the vertical reach of tsunami waves on land) range up to 100 m for the largest paleo-tsunami (NGDC, 2009). In general, the amount of energy tsunami can expend on a reef, adjacent landforms, and human-built infrastructure increases exponentially with increasing tsunami run-up height, and tsunami with run-up depths greater than 10 m cause the most destruction (Okal, 2009). The most vulnerable reef-adjacent landforms are valleys, where subaerial topography contains the wave and elevates the run-up volume. This is most common on reef-fringed continental coastlines or high islands. Numerous studies have highlighted significant local variability in the extent of run-up levels. Indeed the run-up amplitude at any given coast is a complex function of the incident wave characteristics, bathymetry, and coastal topography (Choi et al., 2006; Chavanich et al., 2008; Cochard et al., 2008; Okal, 2009). Plafker's law presents a simple rule of thumb and predicts that maximum run-up does not exceed twice the amplitude of the seismic movement on the fault (Okal and Synolakis, 2004).

The backwash phase is characterized by extreme seaward directed flow, as the unbroken wave is reflected off the land surface or as broken bores drain seaward. However, unlike the run-up phase which is generally perpendicular to the coastline, backwash flow patterns are controlled by

topography, with extreme flows occurring oblique to the shoreline as flow is directed into existing channels (Gelfenbaum and Jaffe, 2003; Umitsu et al., 2007; Paris et al., 2009). These seaward-directed flows are able to preferentially scour coastal landforms but also deliver vast quantities of terrestrial sediment and debris (e.g., trees, building materials) to the coastal margin that promote direct physical impacts on coral reefs (Umitsu et al., 2007; Worachananant et al., 2007; Paris et al., 2009).

In low-lying reef islands, waves can propagate directly across island surfaces as unbroken wave forms as described by Kench et al. (2007, 2008) in the Maldives. Due to the lack of relief in these reef island settings there may be no backwash phase of the wave. Rather, island flood water is ponded on the island surface (Kench et al., 2007). In these circumstances, backwash is not a significant factor in driving change in the geomorphic or ecological structure of coral reefs.

### Impacts of tsunami on coral reef ecology

Paleo-tsunami studies based on interpretation of sediment deposits suggest that mega-tsunami may have catastrophic impacts on reef communities, physically destabilizing and excavating reef coral and framework (Scheffers et al., 2009). However, until the Sumatran tsunami in 2004 very little observational research had been undertaken on the effects of tsunami on the ecology of coral reefs (Brown, 2005; Hagan et al., 2007). A number of studies undertaken immediately following the 2004 event have provided new insights into the types of ecological damage encountered as a consequence of large tsunami events.

Assessments of reef ecological condition following the Sumatran event collectively indicate that tsunami had a relatively minor impact on reef condition and ecological composition when compared with documented impacts of cyclones, bleaching episodes, and anthropogenically-forced change in reef systems (Baird et al., 2005; Brown, 2005; Gunn et al., 2005; Campbell et al., 2007). A number of studies were able to revisit reef monitoring sites that had been established prior to the tsunami, to document specific changes in reef ecological condition. For example, Phongsuwan and Brown (2007) present data from 18 fringing reef sites on the west coast of Thailand and show that at over 60% of sites there was little or no damage to reef ecological condition (Figure 3a). At only 13% of sites were reef communities severely damaged. While gross impacts were considered minor there was ample evidence of dramatic changes in the physical and ecological condition of reefs at the local scale. The range of impacts is described below based primarily on observations from the Sumatran tsunami.

### Earthquake-related impacts

While not a direct impact of tsunami waves, the precursor earthquake of the Sumatran tsunami promoted differential uplift and subsidence of fringing reef systems. It is estimated that 1,000 km of coral reef, along the plate boundary from the Andaman and Nicobar islands to Sumatra, have

been tectonically affected (Bilham, 2005). One of the most dramatic effects on reef systems was uplift of some fringing reefs by 1.6 to 2.0 m on the west coast of the Andaman Islands (Sieh, 2005; Searle, 2006; Liew, 2008). Uplift had a number of impacts on reef communities. First, uplift caused extensive mortality of uplifted corals due to subaerial exposure of reef flat communities (Hagan et al., 2007; Figure 3b). For example, Sieh (2005) reported microatolls were raised by 1.5 m on the northwest coast of Simeulue Island, Aceh Province. Second, uplift raised subtidal reef front coral into the intertidal reef flat zone, which may have medium-term consequences for coral adaptation and survival (Hagan et al., 2007). Associated with uplift, Bahuguna et al. (2008) report the development of cracks in the reef structure. Collectively, such fissures are likely to reduce the structural integrity of the reef system.

In contrast, other tracts of reef underwent subsidence by up to 2.5–3.0 m (Searle, 2006; Hagan et al., 2007), which has displaced shallow water communities to deeper reef zones. While this subsidence has created new accommodation space for coral growth on reef tops (see *Accommodation Space*), there have also been subtle changes in hydrodynamics and water temperatures that may affect species' survival and reef community structure in the medium-term (see *Corals: Environmental Controls on Growth*).

### Tsunami impacts on corals and reefs

Tsunami impact can be differentiated into a number of categories. Mechanical damage to corals following the Sumatran tsunami was observed on many reefs. This included the breaking of coral branches, collapsing of branching colonies and the fracture of massive coral (Baird et al., 2005; Worachananant et al., 2007; Figure 3c and d). This physical breakage of corals is attributed to impacts by water-borne debris during the uprush and backwash phases of tsunami flow. Such debris might include marine and/or terrestrial debris (e.g., trees).

The overturning of individual coral colonies was prevalent in most studies (Figure 3e and f). However, the depth range and types of corals susceptible to overturning varied between studies. For example, Baird et al. (2005) and Campbell et al. (2007) reported that overturning was most common for massive corals at depths greater than 2 m, and which were attached to unconsolidated substrates (Figure 3e). This is consistent with the observation that it is the mechanical strength of attachment of corals to substrate which is of overriding importance in coral stability as opposed to the integrity of the coral growth form (Massel and Done, 1993; Madin, 2005; Madin and Connolly, 2006). Studies from the reefs of Thailand indicated that overturned, massive, and tabulate coral colonies were limited to shallow water sections of reefs (Brown, 2005; Phongsuwan and Brown, 2007; Chavanich et al., 2008; Figure 3f).

Transport of large coral colonies is an additional physical change in coral colonies. Baird et al. (2005) report movements of large massive colonies from the reef front (water

**Tsunami, Figure 3** Types of ecological damage observed on coral reefs following the Sumatran tsunami (26 December 2004). (a) Unaffected mixed coral community on upper reef slope, Surin Islands (From Phongsuwan and Brown, 2007). (b) Uplifted coral reef, Andaman Sea (From unknown). (c) Broken branches in an *Acropora* sp. in 0.5 m water depth (From Campbell et al., 2007). (d) Shattered blue coral *Heliopora coerulea* at 3 m water depth Telok Beluhan, Pulau Weh (From Hagan et al., 2007). (e) Overturned *Porites* sp colony at 4 m water depth, north coast Aceh Province (From Hagan et al., 2007). (f) Overturned table coral at 3 m water depth, Ari atoll, Maldives (From Gischler and Kikinger, 2007).

depths >10 m) to reef flat surfaces (Figure 4a and b). Goto et al. (2007) identified more than 1,000 1 m size coral blocks transported from the reef front to reef flat surface at Pakarang Cape, Thailand.

Sedimentation on reefs is an additional impact reported in most studies. Sedimentation is manifest in a number of ways. First, through deposition of remobilized deeper marine sediments smothering corals as tsunami waves propagated across the reef (Baird et al., 2005; Chavanich, et al.,

2007; Kelletat et al., 2007; Worachananant et al., 2007; Gischler and Kikinger, 2007; Bahuguna et al., 2008; Figure 4c and d) and deposition of terrestrial-derived sediments as a consequence of backwash flow. Deposition can smother living corals and promote coral mortality. Furthermore, at some sites transport of coarser sand and gravel sized sediments buried, or partially buried, corals leading to coral mortality (Campbell et al., 2007; Worachananant et al., 2007; Kench et al., 2008; Figure 4e and f).

**Tsunami, Figure 4** Examples of sediment movement and impacts on coral reefs following the Sumatran tsunami (26 December 2004). (a) Large *Porites* colony, 3 m diameter, transported from the reef and buried in the beach at Pulau Beras, Aceh (From Campbell et al., 2007). (b) *Porites* boulder situated 50 m from beach at Pulau Beras (From Baird et al., 2005). (c) Healthy colony of *Acropora muricata* in 1 m water depth, Aceh, November 2000 (From Campbell et al., 2007). (d) The same colony as in Figure 3c in April 2005. The coral tissue has been smothered by sediment stirred up by the tsunami (From Campbell et al., 2007). (e) *Porites* colony 1.5 m diameter, half buried in coarse sand and gravel at 4 m water depth, Aceh (From Baird et al., 2005). (f) Reef flat corals buried by sand as a result of beach extension across reef flat at Hulhudhoo Island, Baa atoll, Maldives (From author).

Campbell et al. (2007) and Kelletat et al. (2007) also suggest that the sediment transport regime of some reefs has altered as a consequence of delivery of increased sediment volumes to reefs. The constant remobilization of finer material and their smothering effect have caused delayed and localized mortality of corals.

The reported range of ecological impacts resulting from the Sumatran tsunami shows marked differences from the ecological impacts associated with cyclones

(Baird et al., 2005). While cyclone damage is also patchy (Woodley et al., 1981; Done, 1992b; see *Tropical Cyclone/Hurricane*), it is unusual for shallow sections of tsunami-impacted reefs to avoid damage, and fragile colonies (branching and tabular) are generally disproportionately affected compared to massive colonies. Such differences have been attributed to differences in wave energetics as they interact with reefs. Cyclonic waves impact upon reefs repeatedly over periods of several hours. While the

waves may be large, they carry and release their energy at upper layers of the water column and, therefore, impact shallow water reef zones: deeper parts of the reef are often indirectly affected by avalanches (Baird et al., 2005). In tsunami, by contrast, there are generally only a small number of waves generated on any given event. These waves transfer energy throughout the water column so that hydrodynamic stress is transferred directly to greater depths (Yeh et al., 1994), they can remobilize deeper sediments, and they can damage deep slope coral communities. Furthermore, a characteristic feature of tsunami is marked draw-down of water level prior to tsunami impact. Entire subaerial exposure of reef flat surfaces occurred during the Sumatran event. Consequently, as tsunami waves reinvaded the reef, they interacted directly with the reef-top sediments, structure, and coral communities (Kench et al., 2008; Paris et al., 2009).

### Patterns of impact

While individual studies have attempted to interpret the underlying factors that expose reefs to tsunami impacts at the site-specific scale, comparative analysis between studies (at the regional to global scale) suggests simple explanations are not possible. For instance, some studies of the Sumatran tsunami (e.g., Cochard et al., 2008) attributed the apparent localized variability in impact severity to the state of reef health (e.g., Cochard et al., 2008). However, this was not corroborated by studies of many near-field sites in the Andaman Sea, which suggest a threshold of wave energy above which reef condition has little effect on tsunami impacts (Paris et al., 2009). Overturning and transport of massive colonies occurred both at depth in the Acehese reefs (Baird et al., 2005; Campbell et al., 2007) and on shallow reef sites (coast of Thailand; Chavanich et al., 2008). A number of studies report higher rates of damage in reef passages, where currents were forced to accelerate during tsunami wave flow (Goffredo et al., 2007; Worachananant et al., 2007). Foster et al. (2006) showed the highest frequency of overturned corals occurred on fringing reefs inside bays as opposed to headland reefs.

A synthesis of post-tsunami surveys indicates a number of preconditioning factors that make reefs susceptible to damage. These factors include: relative exposure of reefs to wave impact; reef slope and nearshore bathymetry that control wave shoaling and breaking potential; the water depth across the reef surface; the ecological composition of reef communities, and; the substrate type upon which corals are attached. Due to this combination of factors, damage to reef communities is highly variable and difficult to predict (Baird et al., 2005; Campbell et al., 2007; Chavanich et al., 2008).

At issue, in evaluating the long-term consequences of tsunami on reef ecology is whether impacts will persist on reefs. Whereas reef losses to uplift are irreversible, the localized, patchy, and minimal level of the Sumatran tsunami impacts on corals suggests that the reefs there will recover over a 5–10-year period (Baird et al., 2005;

Brown, 2005; Hagan et al., 2007). Such optimistic scenarios are based on the presence of unaffected sections of reef to act as sources of larvae for coral regeneration.

### Geomorphic impacts on reefs and reef associated landforms

Despite the extreme size and speed of larger tsunami and the devastating impacts such events have on coastal communities and infrastructure, few studies have evaluated the geomorphic implications of tsunami. The majority of studies of geological impacts of tsunami have focused on the interpretation of sediment deposits to discriminate the presence, magnitude, and frequency of extreme wave events and their flow characteristics. However, definitively attributing such deposits to tsunami has proved problematic in reef environments because cyclonic wave events produce similar sedimentary units (e.g., Bourrouilh-Le and Talandier, 1985; Nott, 1997). Consequently, the differentiation of paleo-tsunami from other extreme wave event deposits has been the subject of considerable discussion (see Hearty, 1997; Nott, 1997, 2003; Goff et al., 2004; Noormets et al., 2004; Morton et al., 2008; Scheffers et al., 2009).

Tsunami events over the past 20 years, however, have provided modern analogues to improve our understanding of the types of geomorphic change and sedimentary deposits they produce. For example, observations of the erosional and depositional signatures associated with the 1992 event at Flores, Indonesia is one of the earliest attempts to directly examine detailed geomorphic effects of tsunami in a reefal environment (Yeh et al., 1993). Subsequently, a number of studies have examined the sedimentary deposits formed by recent tsunami at Mindanao, Philippines in 1992 (Besana et al., 2004), Rajegwesi, Java, Indonesia in 1994 (Dawson et al., 1996), Papua New Guinea in 1998 (Gelfenbaum and Jaffe, 2003), and most notably the Sumatran mega-tsunami in 2004, on which there have been numerous reports from around the Indian Ocean.

Collectively, these paleo-studies and modern analogues identify a range of geomorphic impacts. These impacts can be divided into those affecting reef structure and those influencing associated reef sedimentary landforms (reef islands and coastal plains adjacent to fringing and barrier reefs). The geomorphic changes in each component of the reef system are mediated by the mobilization, transfer, and deposition of reefal sediment.

### Geomorphic impacts on coral reefs

Uplift or subsidence of coral reefs, as a consequence of earthquakes that trigger tsunami, are major and immediate changes in the gross structure of coral reefs with respect to sea level (discussed above). Based on large volumes of reef-derived material deposited on land, paleo-tsunami studies suggest that mega-tsunami can impact on the living veneer and structure of reefs, decimating living coral communities, and degrading or removing the geomorphic structure of a coral reef. For instance, coral reefs were present on the windward coast of Bonaire and Curaçao in the

Pleistocene and early-mid Holocene, but are currently absent (Pandolfi and Jackson, 2001), manifest instead as approximately 4 million tons of the Holocene remains (coral fragments and boulders) on the adjacent coastal plain (Scheffers et al., 2009). Consequently, the frequency and intensity of large tsunami and other extreme wave events may determine whether reefs can persist, develop, or perish in a particular location (Blanchon et al., 1997; Morton et al., 2008).

While changes in reef structure and elevation may occur at the event timescale (hours), the resulting alteration of the process regime may be of medium to long-term duration (years to centuries). Reef elevation with respect to sea level is a critical control on the ability of reefs to dissipate background ocean wave energy (Roberts et al., 1977; Symonds et al., 1995). As water depth increases at the reef edge, the period of time that incident wave energy can propagate across reefs also increases (Kench and Brander, 2006). It is this energy that is available to entrain and transport sediment on reef surfaces promoting erosion or reconfiguration of island shorelines (Kench et al., 2009). Consequently, geomorphic processes can be expected to close down across reefs as a consequence of uplift in a similar fashion to the closing of the mid-Holocene high energy window (Hopley, 1984). In contrast, geomorphic processes are likely to be reactivated following subsidence or loss of reef structure as water depth over reefs increases, as modeled by Sheppard et al. (2005) (see *Accommodation Space; Climate Change: Impact of Sea Level Rise on Reef Flat Zonation and Productivity*).

### Geomorphic impacts on reef-associated sedimentary landforms

Tsunami can promote a range of geomorphic responses in sedimentary shorelines deposited on or adjacent to coral reefs. Such geomorphic changes are mediated by the redistribution of reefal sediment within the reef system.

Shoreline erosion (net loss of land) is a commonly cited effect of tsunami wave interaction with sedimentary landforms. For instance, extensive erosion of low-lying coastal plains was reported on the coast of Banda Aceh, following the Sumatran tsunami of 2004 (Paris et al., 2009). Apart from places where erosion was arrested by the presence of beachrock, there was a substantial horizontal retreat of the shoreline and destruction of sand barriers protecting lagoons, producing a step-like displacement of the active shoreline. Along a 9.2 km stretch of shoreline at Lhok Nga Bay, the mean rate of shoreline displacement was approximately 60 m and involved reworking of 276,000 m<sup>3</sup> of sediment (Paris et al., 2009). Coastal erosion was also identified at other reef locations throughout the Indian Ocean, although magnitudes of erosion were much less than those at Lhok Nga Bay (e.g., Richmond et al., 2006). Based on a comparison of pre- and post-tsunami surveys of reef island morphology, Kench et al. (2006) found that erosion of the vegetated core of islands in the Maldives ranged from

1–9% of island area (Figure 5). Physical evidence for coastal erosion includes stripping of beaches, development of erosional scarps in the vegetated core of islands, scour and collapse of vegetation at island shorelines, erosional trenches on the lagoon sides of islands, and erosional contacts in terrestrial soil horizons (Figure 6).

Proximity (exposure) to tsunami source is a factor determining the magnitude of coastal erosion. However, like ecological impacts, the magnitude of reported erosion is spatially variable. Other factors influencing the extent of erosion include elevation of the seaward margin of the coast, differences in the way tsunami interacted with the shoreline, the volume of sediment present at shorelines to act as a buffer to tsunami impact, and the presence or absence of vegetation. On fringing reef coasts backed by steep terrain, the shoreline experiences both uprush and backwash flow. Consequently, the coastal deposits experience a combination of landward and seaward-oriented turbulence and sediment transport (Paris et al., 2007, 2009). By contrast, on atoll islands in the Maldives, there was no backwash. Due to the low-elevation of these atoll islands (<2 m above mean sea level), the tsunami waves were able to wash over the outer ridge, the lack of relief precluding backwash. Rather, the basin morphology of island surfaces allowed water to pond for up to 6 weeks after the tsunami (Kench et al., 2007, 2008). Water ponding promoted salinization of the groundwater tables and salt burn of island vegetation. On some islands, this water flowed through the island sands and surfaced on beaches producing gully erosion of the upper beach and vegetated shoreline. In some southern atolls of the Maldives, there was complete overwash of the islands. This overwash produced minimal geomorphic impacts on islands, but it did cause erosional shore-parallel trenches (up to 2 m deep and 5–10 m wide) on the lagoon shorelines of islands (Gunn et al., 2005; Richmond et al., 2006; Figure 6d). These features are thought to result from wave turbulence, which was unable to erode island surfaces due to the dense vegetative cover, but was able to scour loose unconsolidated sediment along the lagoon shoreline.

The volume of sediment stored at the shoreline prior to tsunami impact also plays a significant role in the degree of shoreline erosion. On Maldivian reef islands, where plentiful volumes of sediment were stored in the beaches, this material was able to absorb impact of the tsunami and shoreline erosion was minimal (Kench et al., 2008). By contrast, locations with little or no beach had greater erosion.

Perhaps the most striking geomorphic outcome of tsunami is the creation and aggradation of coastal landforms: the landward deposition of reefal material. The origins and depositional history of these units can be determined using their sedimentary characteristics, extent, and morphology. Landward deposition of sand sheets has been observed on numerous reef-fringed shorelines and low-lying atoll islands, where sediment rich coasts have undergone net erosion (Figures 5 and 7a–d). Typically, sand sheets take the form of landward tapering wedges of sand, which exhibit bedding that results from multiple wave flow

**Tsunami, Figure 5** Summary of geomorphic impacts of the December 2004 Sumatra tsunami on Thiladhoo Island, South Maalhosmadulu atoll, Maldives. Thiladhoo Island in center showing pre- and post-tsunami vegetated shoreline and toe of beach positions. Light gray denotes vegetated island core. Note: erosion of vegetated shoreline along the northwest, northeast shorelines (dark gray); landward movement of toe of beach position on exposed northeast shoreline; extension of depositional zones on the western and southern lobes beyond the surveys previously undertaken at the same stage of the northeast monsoon (January 2002, February 2003); shift in beach position resulting from the southwest monsoon conditions (*dashed line*); and Limit of landward extension of overwash sand sheet deposition (*yellow line*). (a–d) Island to reef topographic surveys showing landward movement of the vegetated scarp (a, b, c) and significant deposition on western lobe smothering live coral on the reef flat (d) (From Kench et al., 2006).

across the land surface (Figure 7c). The landward extent of these sand sheets appears correlated with the magnitude of tsunami, coastal topography, and sediment supply. For example, on Babi Island sand sheets ranging in thickness from 0.05 to 0.1 m extended up to 500 m landward as a consequence of the Flores tsunami in 1992 (Minoura et al., 1997). At Lhok Nga Bay, Banda Aceh, sand sheets were identified up to 3.5 km landward and ranged up to 0.8 m thick following the Sumatran tsunami (Figure 7d). In the Maldives, the same event produced continuous and discontinuous sand sheets up to 0.3 m thick and extending up to 60 m landward on the outer rim of atoll islands (Kench et al., 2006, 2008; Figures 5 and 7). Few examples of such sand sheets have been identified in paleo records suggesting these sedimentary units do not retain their integrity over geological timescales (Kench et al., 2006). However, these deposits are

geomorphically important as they contribute significant quantities of sediment to coastal landforms ( $10^2$ – $10^6$  m<sup>3</sup>) and represent net addition to the land surface. In the context of low-lying reef islands and coastal plains these deposits represent vertical aggradation of the land surface that can become vegetated and occupied by humans. Over geological timescales, the frequency of tsunami may be important in vertical building of reef-associated landforms.

Landward deposited ridges and ramparts comprising a mix of large coral boulders, gravels, and sand-size materials derived from adjacent coral reefs have been attributed to tsunami in a number of studies (e.g., Scheffers et al., 2009; Figure 7e and f). These geomorphic features can be up to 4 m in elevation and 30–400 m in width, thus representing significant additions of material to coastal sediment units ( $\sim 10^6$  m<sup>3</sup>; Morton et al., 2008;

**Tsunami, Figure 6** Examples of shoreline erosion resulting from the December 2004 Sumatra tsunami. (a) Satellite image showing large-scale coastal retreat in the north part of Leupung Bay, Sumatra (From Paris et al., 2009). (b) Lateral scour of reef island shoreline exposing root systems in South Maalhosmadulu atoll, Maldives (From author). Scheffers et al., 2009). In the example of Bonaire and Curaçao (described earlier), landward delivery of the detrital Holocene reef matrix has formed a sequence of ridges and ramparts that extend across several kilometers of the coastal margin. Consequently, individual tsunami rapidly deposit large volumes of reefal material, and the frequency and timing of events determine the long-term development of the morphology of coastal plains. However, considerable debate exists as to whether such deposits are attributable to tsunami or to cyclone waves. Morton et al. (2008) argue, there are no known examples of historical tsunami depositing a laterally extensive, high ridge of coarse clasts in the Caribbean Islands. Furthermore, no such deposits were reported following the Sumatran mega-tsunami. However, Scheffers et al. (2009) propose key discriminatory features such as clast abrasion, internal sedimentary structure, ridge orientation, and width can be used to determine the relative role of the two phenomena in deposit formation.

Boulder fields are perhaps the most commonly cited product of the landward transfer of nearshore material under tsunami flow. In reef settings, paleo studies have identified boulders (reef framework and coral bommies) up to

8 m diameter and weighing more than 260 t (Scheffers et al., 2009). While they represent the addition of very large individual reef blocks to the land surface (Figure 7g and h), they can be quantitatively less important than other depositional forms. Such deposits have attracted great scientific interest as diagnostic indicators of extreme wave events (Morton et al., 2008). Of note, Goto et al. (2007) examined boulder deposits on the west coast of Thailand and found that more than 1,000 coral boulders were transported from the reef front to the reef flat, although none were deposited on land (Figure 7h). A number of studies have highlighted a significant disparity between the physical evidence of geomorphic change observed from the Sumatran mega-tsunami and interpreted paleo mega-tsunami deposits. In particular, paleo-tsunami studies have identified more spectacular boulders (megablocks), more extensive boulder fields, and extensive coarse clast ridges (Scheffers and Kelletat, 2003; Robinson et al., 2006; Kelletat et al., 2007; Morton et al., 2008; Scheffers et al., 2009). Such differences have caused some researchers to question whether the Sumatran event provides a good analogue for the impacts that can be expected from mega-tsunami. Paris et al. (2009) suggest that the geomorphic impact of this event is

**Tsunami, Figure 7** Examples of types of tsunami sedimentation and geomorphic products. (a) Landward limit (60 m) of continuous overwash sand sheet, Dhakandhoo Island, Maldives (From author). (b) Small sand sheet extending across reef island margin, South Maalhosmadulu atoll, Maldives (From author). (c) 0.3 m thick tsunami sand sheet on outer margin of Thiladhoo Island, Maldives (From author). (d) 0.75 m thick sand sheet overlying dark soil horizon (base of trench) at Lampuuk, northwest Sumatra (From Richmond et al., 2006). (e) Seaward front of inferred tsunami ridge along the southern coast of Anguilla (dated at 1,500 years before present; From Scheffers et al., 2009). (f) Inferred coarse clast tsunami deposit, Caribbean. Note chaotic and bimodal texture of internal structure (From Scheffers et al., 2009). (g) Ten tons coral boulder at Nai Harn Noi Beach, Thailand deposited by the Sumatra tsunami (From Kelletat et al., 2007). (h) Large 2 m diameter boulder (one of more than 1,000) deposited at Pakarang Cape, Thailand (From Goto et al., 2007).

more impressive in its spatial extent (influencing many countries around the Indian Ocean basin) rather than its intensity. It has been suggested that the slow impulse movement (7 min) along the fracture zone that generated the tsunami produced a wave train that was less intense than major paleo-tsunami (Kelletat et al., 2007).

## Summary

Tsunami are extreme wave events that can be devastating to coastal communities. These events, while infrequent on human timescales, are relatively common at geological timescales and have impacted on global reef systems throughout the history of their geomorphic development. The impact of tsunami on coral reef systems has largely been interpreted from paleo-tsunami reconstructions and in more recent years studies of modern tsunami impacts. In this regard, the Sumatran mega-tsunami has provided a rich source of analogues. Collectively, these studies have identified a wide range of ecological and geomorphic impacts on reef systems ranging from paleo interpretations of total reef destruction and transfer of debris to build coastal landforms to minimal ecological and geomorphic impacts. Indeed, the tragic Sumatran mega-tsunami in 2004 generally had relatively minor ecological and geomorphic impacts on reef systems, despite spectacular localized impacts. Such results signify either misinterpretation of impacts in paleo studies or simply that deposits represent the outcomes of even larger extreme wave events.

Studies highlight extreme spatial variation in magnitude and type of tsunami impact. Underlying factors that predispose reefs and reef landforms to impact include: tsunami wave height; ocean bathymetry, reef morphology and health; coastal topography; sediment volume stored at the shoreline, and; coastal vegetation.

While many of the ecological and geomorphic impacts identified represent immediate responses to extreme wave forces, these changes may also trigger longer-term changes in ecological and physical process regimes that can impact reef systems. Examples include the increased flux of sediment on reef systems that may reduce water quality and impact on reef health; a shift in energetics of reef hydrodynamic processes, and; disruptions in sediment budgets and, therefore, geomorphic equilibrium of reef landforms (Kench et al., 2008).

At geological timescales, coral reefs and reef-associated landforms have been subject to multiple tsunami throughout the history of their geomorphic development. Consequently, the frequency and magnitude of events is likely to not only control reef persistence but influence development of sedimentary landforms. However, few studies have been able to elucidate these dynamics beyond the role of individual events.

## TURBID-ZONE AND TERRIGENOUS SEDIMENT-INFLUENCED REEFS

Chris Perry  
 Manchester Metropolitan University, Manchester, UK

## Definition

*Turbid-zone and terrigenous sediment-influenced reefs.* Coral reefs that develop in environments that are either directly, or indirectly, under the influence of terrigenoclastic sediments. Direct influence is exerted in those sites where high levels of terrigenoclastic sediment accumulation or sediment flux occur. Indirect influence is exerted where fine-grained sediments are continuously or episodically in suspension, thus influencing reef development by elevating

turbidity levels. Typically, the reefs developing under these conditions are more restricted both spatially and bathymetrically than their clear-water counterparts, but can still harbor thriving and relatively diverse coral communities and exhibit high coral cover. Such reefs also represent important localized sites of carbonate production within otherwise terrigenous sediment-dominated marine environments.

## Introduction

High levels of terrigenous sediment input and elevated turbidity regimes have been widely identified as a major limiting factor for coral reef development (Buddemeier and Hopley, 1988). These limitations have been linked not only with the ongoing supply of terrigenoclastic sediments from adjacent mainland (fluvial) sources, but also with past phases of terrigenous sediment accumulation (especially reworking of relict lowstand fluvial sands and gravels, and soils) and with ongoing sediment flux within the marine environment. The various sources or pathways of terrigenoclastic sediment input and influence vary in significance within different marine settings and act to influence reef development in different ways over a range of temporal and spatial scales. In some environments, major changes to catchment sediment yields, often linked to changing land-use practices, can exert a major influence on coral community structure and reef zonation, especially where the modified marine environmental conditions far exceed the background conditions under which the existing reef communities evolved (e.g., Cortés and Risk, 1985). Under such conditions, studies predict identifiable shifts in coral cover, diversity and growth rates, and change in coral fecundity (reviewed in Fabricius, 2005). Often, the timescales and longevity of any such changes are complex to predict and may depend upon the adaptability of the coral community. In this context, several studies have documented the resistance mechanisms utilized by corals to cope with “high” sedimentation rates (reviewed in Sanders and Baron-Szabo, 2005), while other studies have documented shifting feeding regimes (changes from predominantly phototrophic to heterotrophic feeding strategies) under higher turbidity conditions (Anthony, 2000, 2006).

However, where the timescales of terrigenous sediment input/accumulation are rather longer, and where coral communities have developed that are more adapted to deal with the ongoing/episodic stresses imposed by high-sediment input/flux regimes, ecological impacts may be less apparent (e.g., Perry et al., 2008). Indeed, the long-term (millennial timescale) persistence of coral reefs within modern marine environments that are under direct terrigenoclastic sediment influence, combined with the numerous descriptions of mixed carbonate (reefal):terrigenoclastic facies in the rock record, provides clear evidence not only of the potential for corals to settle and colonize sedimentary substrates under these conditions, but also for sufficient rates of carbonate framework and sediment production to allow both vertical reef growth and lateral reef accretion.

The reefs that form in these environments represent important localized sites of carbonate production and

biodiversity within areas otherwise dominated by terrigenoclastic sediment accumulation. They form within a wide range of coastal and shallow marine settings (e.g., along open sedimentary coastlines, within muddy coastal embayments, and around high continental islands), have established above a wide range of sedimentary substrates (subtidal sands and muds, deltaic sands, and gravels), and can be delineated from their clear-water counterparts on the basis of their geomorphology and their internal facies/framework fabrics. Available evidence suggests that reef development in these settings may be somewhat opportunistic, with reefs establishing in areas of low net sediment accumulation, but that once established they can grow rapidly to sea level through often narrow vertical accommodation space windows (see Chapter *Accommodation Space*). In some settings, where seafloor substrates permit, such reefs undergo significant seaward progradation, with accretional/progradational histories lasting over millennial timescales despite ongoing terrigenous sediment influence. In other cases, more episodic phases of reef “switch on” and “switch off” may occur as a function of more limited vertical and seaward accommodation space availability and/or nearshore sediment morphodynamics. Given the clear potential for reef building to occur under these conditions, the widespread view that terrestrial sediment inputs inherently suppress or inhibit reef-building potential is probably too simplistic. Rather it is better to consider the reefs that develop in these settings as being one type of a spectrum of reef-building states that are controlled by prevailing marine environmental conditions (see Perry and Larcombe, 2003).

## Terrigenoclastic sediments and turbidity as a limit to coral reef growth

As outlined above, the input and accumulation of terrigenoclastic sediments, and any associated reworking or flux of fine-grained sediment that results in elevated turbidity regimes, can act as a limiting factor to coral growth and reef development. The nature of, and controls upon, these limiting factors and their potential to impact coral survival and reef development are, however, markedly different. Specifically, terrigenous sediment inputs can impact upon coral growth and survival in two main ways: by elevating sedimentation rates and by increasing water turbidity.

## Sedimentation

Sediment accumulation (the downward flux and deposition of sediment on the seabed) can impact upon coral physiology because of the excessive energy requirements made on corals by sediment rejection mechanisms. Under highly elevated rates of sediment accumulation complete burial of corals can occur and, if of sufficiently long duration, this will result in coral death. Where this accumulating sediment is reworked on the seabed the potential for soft tissue abrasion and polyp mortality is high, and this will likely inhibit coral larval settlement. Most typically,

high sedimentation rates are associated with inputs of sediment from proximal fluvial sources, most typically under flood conditions. However, in some environments, terrigenous sediment accumulation primarily represents a legacy of lowstand shelf soils and fluvial sediments that were reworked during the Holocene transgression and transported landward during shelf flooding. In this way, long-term, net terrigenous sediment accumulation can act as an important limiting factor to reef development and a strong control on regional patterns of turbid-zone reef development (discussed below). Threshold sedimentation rates for coral survival are very varied, but widely reported and quoted levels ( $1\text{--}10\text{ mg cm}^{-2}\text{ d}^{-1}$  – slight to moderate impacts;  $10\text{--}50\text{ mg cm}^{-2}\text{ d}^{-1}$  – moderate to severe impacts;  $>50\text{ mg cm}^{-2}\text{ d}^{-1}$  – severe to catastrophic impacts; see Pastorok and Bilyard, 1985) appear to be too low in terms of any short-term (ecological timescale) impacts upon coral growth. These rates can often be exceeded on many inshore coral reefs and would indicate some degree of sedimentation impact even on mid- to outer-shelf reefs (see Hopley and Choat, 1990). A key factor in this context is, however, likely to be the volume, intensity, and duration of any input event, set both against the potential for sediment flux and reworking during and after the event, and against the background sediment accumulation rate. At sites on the inner Great Barrier Reef Shelf, for example, it has been suggested that the resuspension of terrigenous sediment already deposited on the shelf far exceeds that derived from recent fluvial inputs, the latter being relatively insignificant in terms of modifying the sedimentary regime in the region (Larcombe and Woolfe, 1999). An additional, but important, point to make here is that data obtained from sediment traps do not, in many environments, provide a realistic estimate of actual net sedimentation rates because they do not factor in sediment resuspension potential.

### Turbidity

High levels of turbidity, associated either with inputs of fine-grained sediment that are held in suspension in the water column and/or the reworking of seafloor sediments, will primarily impact coral physiology by reducing light levels such that they interfere with algal photosynthesis within the coral tissue. One of the main effects of this is to reduce the depth of the photic zone, effectively raising the “photic floor” (the maximum depth of photosynthesis) so that the depth range for potential reef development becomes bathymetrically constrained. One obvious cause of such high turbidity events is from flood plumes, where large volumes of fine-grained sediment are held in suspension close to the water surface. The extent and duration of these pulsed inputs are clearly dependent upon the magnitude of the flood event, sediment availability within the catchment, and nearshore wave/current patterns that will dictate the spatial extent and mobility of any flood plume. Devlin and Brodie (2005) illustrate the spatial extent of various flood plumes on the Queensland coast, and it is

clear that flood plume distributions vary significantly between events. High-turbidity regimes also result from the resuspension of seafloor fine-grained sediments (originally derived either from riverine inputs or relict lowstand sedimentary deposits), events that have been shown to be strongly influenced by increases in significant wave height (Larcombe et al., 2001). The result of this can be prolonged periods of elevated turbidity regimes that significantly reduce light penetration, thus acting as an important ongoing influence on reef development.

Threshold levels for coral growth under different turbidity regimes are not established and probably vary on a site-by-site and species-by-species basis, but high suspended sediment concentrations (SSCs) have been reported in the vicinity of many inshore reefs along Australia’s Queensland coast. For example, data from sites around Paluma Shoals, indicate that the reefs experience prolonged high turbidity events with recorded SSCs of up to  $175\text{ mg/l}$  and levels  $>40\text{ mg/l}$  estimated to occur for  $>40$  days per year (Larcombe et al., 2001). At Middle Reef, Larcombe et al. (1995) report SSCs in excess of  $5\text{ mg/l}$  for 53% of the time,  $>10\text{ mg/l}$  for 24% of the time, and  $20\text{ mg/l}$  for  $>9\%$  of the time. Much higher SSCs have been identified from long-term temporal datasets from sites around Luggar Shoal where SSCs exceeded  $50\text{ mg/l}$  for  $\sim 55\%$  of the time and  $500\text{ mg/l}$  for  $\sim 19\%$  of the time (SSCs in excess of  $800\text{ mg/l}$  occurred  $\sim 9\%$  of the time) (Whinney, unpublished data). An additional, but significant, point to make in relation to the above is that even given uniform sediment input regimes and seafloor sediment textural characteristics, marked inter and intra-site variations in sedimentation–resuspension regimes will occur depending upon tidal regime and phase (and thus water depth) and degree of exposure to wave energy (see data in Larcombe et al., 2001; Wolanski et al., 2005). As a consequence, the position of the photic floor as well as the threshold depths across which net sedimentation–net resuspension regimes operate will fluctuate markedly through individual and spring-neap tide cycles (Wolanski et al. 2005; see Figure 1).

### A framework model for understanding reef development under conditions of terrigenous sediment accumulation and elevated turbidity

The longevity and magnitude of factors such as terrigenous sediment input, accumulation, and turbidity, as outlined above, clearly interact to control the potential for reef development. On this basis, Woolfe and Larcombe (1999) developed a conceptual framework model within which to consider the controls exerted by these factors on reef-building potential. This conceptual model was based upon a number of key assumptions about coral settlement, establishment, and reef growth with respect to regimes of sediment production, accumulation, and export: (1) that for reef initiation to occur, the rate of terrigenous sedimentation and the rate of reefal production of carbonate must be near zero, because there is no pre-existing reef activity, (2) that immediately after initiation, reefal carbonate production

**Turbid-Zone and Terrigenous Sediment-Influenced Reefs, Figure 1** (A) Spatial and bathymetric variations in zones of net sedimentation and resuspension. Note that the boundary depth between these zones is much lower in leeward settings and also that in both windward and leeward settings the depth of this boundary zone moves vertically (assuming constant wave-energy levels) depending on tidal phase and height (shw – spring tide high water; slw – spring tide low water; nhw – neap tide high water; nlw – neap tide low water). Adapted from Wolanski et al. (2005). (B, C) Hypothetical variations in the depth of the photic floor in turbid-zone reef settings under spring (B) and neap (C) tide phases. Note that the depth of the photic floor will shallow significantly during periods of increased significant wave height, and that it is even possible that during spring high tides the photic floor may be above the surface of the reef flat.

must exceed non-framework sediment accumulation, or young corals will be overwhelmed and buried. This is a valid assumption, although the high volumetric proportion of terrigenous sediments within the basal facies of many turbid-zone reefs suggests that the balance in favor of reefal carbonate production may only be narrow, and (3) that the balance between reefal framework production and non-framework sediment accumulation must remain essentially positive throughout reef accretion.

These assumptions were used to produce a framework diagram based on the relative rates of reefal (framework) carbonate accumulation (R) and non-framework sediment accumulation (T) (Figure 2), within which a field for potential reef accretion can be delineated. These ideas are clearly conceptual in nature, but provide a framework within which the conditions required for turbid-zone reef growth, in the context of regimes of framework accumulation vs. removal, and terrigenous and non-framework sediment accumulation and removal, can be considered.

Placing quantitative constraints on the various accretionary and erosional parameters outlined above has not yet been feasible (see Woolfe and Larcombe, 1999 for a discussion), but it is clear that terrigenous sediment inputs and accumulation act not only to control the location and extent of reef development, but also styles of reef development and, within reef environments, reef community zonation patterns. These differences are evident not only at regional scales (see, e.g., Done, 1982), but also over much

smaller spatial scales dictated by proximity to sediment source areas. For example, fluvial inputs of siliciclastic sediments have been shown to control the depth and extent of reef development along the NE coast of Barbados, with reef development becoming more limited with proximity to the point sources of siliciclastic sediment input (Acker and Stearn, 1990), and at sites along natural gradients of terrigenous sediment stress in Puerto Rico where marked shifts in community zonation and coral cover occur along this gradient (Acevado et al., 1989).

### Geomorphic settings and styles of turbid-zone reef development

While terrigenous sediment inputs and/or a legacy of their past input thus exert an important control on coral reef development, it is clear that terrigenous sediment-influenced reefs occur within a wide range of coastal and shallow marine environments, and that reef initiation in these environments can occur above a wide range of sedimentary substrates (e.g., Smithers et al., 2006). In addition, the occurrence of mixed carbonate (reefal): siliciclastic facies in similar settings in the fossil record indicates that such interactions are far from isolated contemporary examples – these fossil reef examples are considered in a detailed review by Sanders and Baron-Szabo (2005). Inevitably, all reefs that develop under conditions of terrigenous sediment influence do so in settings with different shoreline geometries, above a range of sediment substrates and are subjected to varying levels

**Turbid-Zone and Terrigenous Sediment-Influenced Reefs, Figure 2** Framework model of conceptual existence fields for coral reefs in relation to the relative rates of reefal (framework) carbonate (R) and terrigenous and non-framework sediment (T) accumulation. The model delineates fields of net erosion (lower left box) and net accumulation (upper right box). Coral reefs are restricted to the central right hand side of the diagram. Turbidity levels increase away from the x-axis ( $T = 0$ ) associated with either sediment accumulation from turbid water ( $T > 0$ ) or erosion of pre-existing substrates ( $T < 0$ ). "Clear water" reefs plot close to the x-axis and turbid reefs further away. Adapted from Woolfe and Larcombe (1999).

of sedimentation and turbidity influence. Thus, the extent and style of reef-building vary markedly between environments. Three examples below illustrate the diversity of setting, form, and structure that can occur under these varying conditions.

#### Example 1: Muddy, coastal embayment site: South Thailand

Numerous fringing reefs are developed with coastal embayments along the SE coast of Phuket, Thailand, and grow in environments dominated by terrigenoclastic sedimentation (Tudhope and Scoffin, 1994). The main sources of terrigenous sediment are rivers flowing into the semi-restricted Phangnga Bay, and the transport and resuspension of muds results in a strong gradient of turbidity through the bay (underwater visibility ranging from  $<1$  m at innermost bay sites to  $>10$  m outside the bay). Reefs developed in the inner, muddy, and highly turbid areas have reef flats up to 300 m wide and narrow (2–5 m deep) reef fronts, with coral communities dominated by large *Porites* and *Goniastrea* colonies. Much of the internal structure of these

reefs comprises massive, in situ *Porites* and faviid corals, between which a muddy branched coral rubble facies occurs. Radiocarbon dating indicates that reef growth at these sites initiated  $\sim 5,000$  year BP, when sea levels were  $\sim 0.8$  m above present. Reef growth, mostly thorough progradation, has continued to the present, at rates of  $\sim 40$  mm/year. Unusually, reef progradation has been aided by the splitting, toppling, and regeneration of massive reef-front corals – a process driven by the deep boring effects of *Upogebia* sp. shrimp (Tudhope and Scoffin, 1994). The result of reef growth in these settings has thus been the development of laterally extensive, but vertically restricted, reef units above unconsolidated fine-grained terrigenous sands and muds.

#### Example 2: Leeward, barrier island setting: Inhaca Island, southern Mozambique

Narrow fringing reefs and coral communities are intermittently developed along the seaward margins of wide (up to 500 m) intertidal flats that fringe the western (leeward) margins of Inhaca Island, a large siliciclastic sand barrier

island complex, located along the seaward margins of the large estuarine Maputo Bay in southern Mozambique. These shallow nearshore environments are subject to high turbidity levels (which reduce light levels to <5% at depths of ~8 m) and to the effects of periodic smothering and burial of corals associated with a mobile, siliciclastic-dominated sediment substrate (Perry, 2003). These constraints limit coral community development both spatially and bathymetrically, and historical time-scale evidence suggests that the main sites of coral growth presently shift over decadal timescales as a response to periodic sediment remobilization (Perry, 2005). Such rapid rates of turnover restrict the development of rigid framework deposits and, in contrast, the main depositional product of coral growth is branched (mainly *Acropora* sp.) coral rubble – rubble production probably being aided both by intense internal bioerosion (sponge, bivalve, and worm traces) and by periodic storm damage. Much of this rubble accumulates along the margins of the intertidal channels where coral communities are developed and provides a substrate for subsequent coral recruitment. Cores recovered across the present reef-intertidal zone indicate, however, a long-term history of coral community occurrence in this siliciclastic sediment-dominated environment. The internal fabric of the reef comprises a coral rubble floatstone facies dominated by branched coral rubble (often heavily bioeroded, but sparsely encrusted), along with spheroidal rhodoliths and molluscan fragments set within a poorly sorted, mixed siliciclastic:carbonate sediment matrix. Radiocarbon dates indicate that most of the rubble deposits date from the period 6,500–4,700 years BP (Perry, 2005), corresponding to a period of regional sea-level highstand, and which appears to have been a period of rapid reef flat progradation (average progradation rate of around 0.2 m/year). Over the subsequent 4,700 years, progradation of only around 25 m has occurred. This may be attributed to reworking and erosion of the seaward margin of the deposits during periods of fluctuating sea level between 4,700 and 900 years BP, or to a lack of seaward accretionary potential – in this case resulting from significant long-shore current reworking of the accumulating substrate.

#### Example 3: Open sedimentary coastal setting: Paluma Shoals, inner-shelf, Great Barrier Reef

A number of distinct turbid-zone coral reefs have recently been reported from nearshore sites within Halifax Bay, north Queensland, Australia. Of these, Paluma Shoals is the best documented and occurs in an area with episodically high turbidity levels (SSCs of up to 175 mg/l and levels >40 mg/l estimated to occur for >40 days per year; Larcombe et al., 2001). This results from periods of increased significant wave height and fine-grained sediment resuspension (Larcombe et al., 2001). Paluma Shoals comprises a series of reef flats that are subaerially exposed at lowest astronomical tide level, and two main areas of reef development can be delineated: a northern

shoal complex that is attached on its landward side to wide siliciclastic-dominated intertidal sandflats and a southern shoal that is presently slightly detached (Smithers and Larcombe, 2003). The reefs have developed with this shallow, terrigenoclastic-dominated nearshore environment above a basal Pleistocene clay substrate, with reef growth initiating about 1,600 years BP (Smithers and Larcombe, 2003). These reefs have subsequently grown rapidly to sea level and undergone phases of both seaward progradation and leeward infilling. While the present reef flat surface is dominated by *Porites* and *Goniastrea* bommies, much of the internal fabric of the reef comprises a branched coral rudstone-floatstone, with coral clasts set within a matrix of fine-grained terrigenoclastic sediments. These, and other similar reefs, have developed in a narrow zone of low net sedimentation, but high sediment resuspension, along the very innermost areas of the Great Barrier Reef Shelf. Recent data indicates, however, that similar styles of rapid reef emplacement, under similar turbidity-sedimentary regimes, occurred in this region at different periods through the late Holocene highstand (Perry and Smithers, 2010).

#### Reef facies and framework fabrics in turbid-zone and terrigenous sediment-influenced environments

Data both from the reef sites discussed above, and other types of nearshore settings in which turbid-zone reefs have developed (e.g., Johnson and Risk, 1987; Partain and Hopley, 1989; Kleypas, 1996), highlight the potential for long-term (millennial timescale) persistence of coral communities in settings intimately associated with terrigenous sediment accumulation. Commonly, these reef deposits are characterized by thin sequences of mixed coral rubble and siliciclastic-rich sediment facies. These are distinct from those forming under “clear water” conditions, and there is thus some potential to distinguish these turbid coral communities as distinct forms of fringing reef systems (see also Kennedy and Woodroffe, 2002). The framework facies themselves can be distinguished from those associated with “clear water” reef environments in several ways: (1) by the lack of a rigid reef framework either comprising in-situ coral or encrusted coral rubble, (2) by the distinct lack of rubble encrustation/syn-depositional cementation, and (3) by the predominance of a siliciclastic-rich sediment matrix. The composition and structure of such deposits will, however, depend upon subtle differences in local environmental conditions, e.g., sediment compositions, sediment transport and reworking rates, sedimentation rates and turbidity levels. These are likely to produce a gradational range of depositional environments and as a result a range of “turbid-zone” coral depositional facies that reflect differences in the type, longevity, and magnitude of sediment-related stress events (Figure 3). These differences may be evident either at the community/facies level or at the level of the individual colony.

**Turbid-Zone and Terrigenous Sediment-Influenced Reefs, Figure 3** Conceptual diagram illustrating the impacts of sedimentation events of different intensities and durations on corals and coral communities. Adapted from Sanders and Baron-Szabo (2005).

### Temporal and spatial variations in turbid-zone reef development: a regional perspective based on the Great Barrier Reef Shelf

While it is clear that individual turbid-zone reefs can develop within a range of nearshore and inner-shelf locations, and that these clearly demonstrate the potential for reef initiation and growth within terrigenous sediment-dominated inner-shelf environments, it is also useful to consider the nature and influence of large-scale regional terrigenous sediment controls on the location and timing of reef development. This provides a useful insight into turbid-zone reef development on a range of temporal and spatial scales. In this context, the conceptual model developed by Larcombe and Woolfe (1999) that considers the regional location of reef development across the central Great Barrier Reef Shelf provides a useful case study. This model, which was based on assessments of shelf processes, sea-level history, cyclone influence, and sedimentary dynamics on the Great Barrier Reef (GBR) Shelf, Australia, delineated different types of inner-shelf coastline (accretionary and erosional; see Figure 4) and considered the resultant position of the inner-shelf terrigenous sediment wedge as a primary control on reef

establishment. The terrigenous sediment wedge is a body of sediment that accumulated within the inner-shelf areas during the late Holocene transgression and highstand, and it extends out to depths of ~15 m.

Along sections of the coast undergoing net accretion, the sediment wedge is mainland-attached (Figure 4). High net sediment accumulation rates in these areas prevent nearshore reef establishment – and thus, in these areas of the shelf the model suggests that reef accretion is only possible along the inner mid-shelf boundary (i.e., at depth) or around high inner-shelf islands. The existence of reefs along the inner mid-shelf boundary (presumably submerged or relict features) has not been established, but there are a number of examples of reefs that have developed around high inner-shelf islands just within or outside the seaward limits of the terrigenous sediment wedge. These include the reefs described from Fantome Island (Johnson and Risk, 1987) and Pioneer Bay, Orpheus Island (Hopley et al., 1983), which clearly accreted (at least during the early phases of reef development) under terrigenoclastic sediment influence.

In contrast, along erosional coastlines the sediment wedge is mainland-detached (Figure 4), and thus reef growth becomes possible along narrow landward zones of

**Turbid-Zone and Terrigenous Sediment-Influenced Reefs, Figure 4** Conceptual model for inner-shelf turbid-zone reef development on the GBR (adapted from Larcombe and Woolfe, 1999). *Bold boxed* areas highlight the predicted zones in which inner-shelf reef initiation and growth may occur within different coastal sectors.

low net sediment deposition, or again along the inner mid-shelf boundary or around high inner-shelf islands. Several examples of reefs that occur along the mainland coast exist in the literature; some of which are relatively young having initiated and accreted in the last 1–2,000 years, e.g., Paluma Shoals (Smithers and Larcombe, 2003) and Lugger Shoal (Perry and Smithers, 2006), while others established and grew much earlier during the late postglacial transgression and early highstand (e.g., the reefs at Cape Tribulation; Partain and Hopley, 1989). Through the mid-late Holocene sea-level rise and highstand the windows of opportunity for inner-shelf reef establishment and growth, as controlled by the position of the terrigenous sediment wedge, would have changed as the shelf flooded – resulting in marked temporal and spatial variations in reef establishment and accretion potential across the shelf (recently reviewed by Perry and Smithers, 2010). While these ideas have been based upon considerations of the GBR shelf, and have only recently started to be tested in detail, they demonstrate the important influence that long-term patterns of terrigenous sediment accumulation can exert on the location, the timing of, and the potential for, turbid-zone reef development at regional spatial scales.

### Impacts of increased terrigenous sediment yields

While a wide range of environmental and anthropogenic factors have been identified as drivers of late Holocene coral reef community change, elevated sediment (and associated nutrient) yields from anthropogenically modified coastal catchments are commonly implicated. Much of this relates

to the concepts associated with coral-macroalgal phase shifts (see Done, 1992), whereby poor water-quality conditions (including those deriving from high sedimentation and turbidity regimes) may prevent reestablishment of hard coral cover following coral mortality events by promoting a shift to macroalgal dominance. While there is very clear evidence for land-based sediment run-off exerting a very deleterious effect on coral reef “health” (Cortés and Risk, 1985) and rates of reef carbonate production (Edinger et al., 2000) in some areas, the issue is less clear-cut in other regions/sites where clear links between reef community states and water quality changes are complex to establish. At the heart of this lies the very real difficulty in quantifying sedimentation–resuspension–turbidity regimes (discussed above) and the way these parameters interact with coral communities. It is also made difficult by the short timescales over which detailed coral community data, sufficient to allow temporal assessments, are available. In fact, it is perhaps more likely that the nature and magnitude of any community changes and/or patterns of coral community susceptibility, that are directly linked to water quality regime changes, will vary between reef sites and spatially across and along regions, and a number of factors may influence such susceptibility. These include (1) reef proximity to the point-sources of sediment input, (2) the frequency and magnitude of episodic (i.e., flood plume-related) events that can deliver nutrient-enriched waters and suspended sediments to reefs, and (3) perhaps most importantly, the background (or baseline) community structure of the reef (Done et al., 2007). In this final respect a particularly important issue will be the

background environmental conditions under which reef growth has occurred, i.e., the baseline environmental conditions in terms of terrigenous sedimentation (and nutrient) influence to which individual reef communities have adapted during early reef initiation and subsequent growth (see, e.g., the various “impact” scenarios outlined in Figure 3).

While these water quality issues are relevant to many tropical coastlines, the issue has particular high-profile significance to the Great Barrier Reef lagoon, where catchment erosion and fluvial sediment transport rates are reported to have increased markedly since European settlement (from ~1850 AD). Sediment delivery to the inner GBR lagoon is suggested to have increased five- to tenfold since this time (McCulloch et al., 2003), and recent modeling suggests that total nitrogen discharge has increased by a factor of 4, and nitrate and total phosphorus by a factor of 10 (Devlin and Brodie, 2005). The magnitude of these reported and modeled increases has, not surprisingly, raised concerns about the implications for inner-shelf coral reef communities [see Hutchings et al. (2005) and references therein]. However, the extent of any such impacts remains controversial (Larcombe and Woolfe, 1999; McCook, 2001), and debate has persisted, in large part, because long-term (>decadal timescale) coral community data that clearly document temporal community responses under changed sediment or water quality regimes have not, until recently, been available.

However, recent work in this area is starting to provide some perspective on long-term temporal community trends, at least within sites of long-term net terrigenous sediment influence. Perry et al. (2008, 2009), for example, have recently developed millennial timescale records of coral assemblage composition from nearshore sites that have been under fine-grained terrigenous sediment influence throughout their growth history. At these sites, coral community structure appears to have changed little during reef accretion, with the major changes in the presence of reef-building taxa occurring as the reefs have shallowed and reef flats have evolved. A key factor facilitating long-term coral assemblage persistence (stability) at these sites may well be a pre-existing adaptability to deal with the effects of long-term light and sediment “stress” (Stafford-Smith and Ormond, 1992; Anthony, 2000, 2006), with reef building dominated by a few key sediment/light-tolerant taxa. Other records, from other similar sites, are currently being developed and should help to provide a perspective on regional patterns of turbid-zone reef development at different time/space scales. In terms of reef-building potential and in terms of the potential susceptibility of coral assemblages to any changed water quality regime, the most important issue may, therefore, not simply be proximity to the point sources of input, but the composition of the existing coral community and the nature of the pre-existing (baseline) environmental conditions under which reef growth occurred. In more distal (offshore) sites, where contemporary sedimentation–turbidity regimes differ from

those experienced during earlier phases of reef growth the community response patterns may be different – again, this is an area of ongoing research.

## Summary

Recent studies are providing an improved understanding not only of the controls on, but also the dynamic nature of, terrigenous sedimentation, resuspension, and turbidity within nearshore marine environments, and how these parameters fluctuate in and around coral reefs. The key issue that arises from such studies is the need for consideration of the marked variability that occurs spatially (between and across individual reef systems) and temporally (within reef systems/sites). The implications of this are that all turbid-zone and terrigenous sediment-influenced reefs are subject to varying degrees of sediment/turbidity stress. Consequently, the responses exhibited by coral communities and the facies that accumulate are highly site specific. Although the dynamics of sedimentation are often complex, short-term wave-driven sediment resuspension can generate turbidity regimes that far exceed perceived threshold levels for coral survival, while over longer (centennial to millennial) timescales, the landward transgression of inner-shelf terrigenous sediments can control regional patterns of reef establishment.

It is, however, clear that turbid-zone reefs can develop within a wide range of nearshore and coastal depositional environments, with the earliest coral colonizers clearly exploiting a wide range of, often unconsolidated, sediment substrates, including clays, alluvial sands/gravels, and intertidal and subtidal sands and muds (see Smithers et al., 2006; Perry and Smithers, 2009). However, once established, these reefs demonstrate the potential for relatively rapid growth, exhibiting both rapid accretionary and progradational growth modes. Reef facies in these environments typically demonstrate that reef accretion has occurred under conditions of net (often fine-grained) terrigenoclastic sediment accumulation (and are characterized by detrital coral rubble set within a mixed carbonate–siliciclastic matrix). Recent studies also demonstrate that reef building in these environments can be dominated by persistent (but taxonomically restricted) suites of coral taxa, with marked faunal transitions only occurring once the reefs reach sea level and reef flat communities evolve. The long-term tolerance of corals to, at least episodically, high turbidity levels is probably aided by the ability of some corals to switch from predominantly phototrophic to autotrophic feeding modes. These issues are clearly of fundamental importance to understanding the long-term ecological stability of turbid-zone coral reefs and for understanding coral community level responses to sediment flux. Much remains to be learnt, however, about the interactions that occur between reef growth, sea-level fluctuations, and shoreline morphodynamics in these environments, and how these interact to control rates, styles, and the longevity of reef building.

## UNDERWATER LANDSCAPE MOSAICS

---

R. Pamela Reid  
University of Miami, Miami, FL, USA

### Synonyms

2-D mosaics

### Definition

An underwater landscape mosaic is a composite of many overlapping, nadir-view underwater images to form a single large image that provides a “landscape” view of the seabed.

### Introduction

Coral reef ecosystems worldwide are presently threatened by increasing human and natural levels of disturbance (Gardner et al., 2003; Pandolfi et al., 2005; Aronson and Precht, 2006). Current state-of-the-art techniques in coral reef assessment rely on highly trained scientific divers to measure indices of reef health (e.g., substrate cover, species richness, coral size, coral mortality). These indices are commonly derived from line or belt transects, photo-quadrats, or strip video mosaics. Limitations of these approaches include the need to employ highly trained scientific divers/coral reef ecologists, restricted dive time, and spatially inaccurate underwater imagery with a limited footprint. These limitations are addressed by recent advances in underwater landscape mosaic technology (Lirman et al., 2007; Gintert et al., 2009).

A mosaic is a single large image composed of many overlapping images each covering a small portion of the total area. Individual underwater images taken close (~1–2 m) to the seabed have high spatial resolution and minimize water column attenuation but cover only a small area. Mosaics enable a larger area to be viewed in a single

image, thereby not only providing the clarity and resolution of individual pictures but also affording a “landscape view” of the seabed. Near-nadir (downward looking) images are used to create a map-like overhead view of the seabed in which the scale does not vary appreciably across the mosaic.

Current underwater landscape mosaic technology, which uses a combination of video and still images (e.g., Gintert et al., 2009), enables creation of meter-scale maps of reef plots and high resolution images (sub-millimeter-scale) of individual coral colonies (Figure 1). Users can collect imagery for areas of several hundred square meters in under an hour of in-water dive time.

### Background

Pizarro and Singh (2003); Singh et al. (2004); and Ludvigsen et al. (2007) provided brief histories of the development of underwater mosaics. Despite the fact that underwater mosaics have been made for many years, they have not been used routinely for ecological studies until recently for two reasons. First, mosaics have historically required tremendous manual effort to construct, using either physical manipulation of images (Ballard, 1987), digital “photoshopping” (Anonymous, 2001), or interaction with photogrammetric software (Gifford, 1997). Second, imagery used to create underwater mosaics has traditionally been acquired from submersibles or remotely operated vehicles (e.g., Ballard et al., 2002), most often requiring the deployment off acoustic positioning arrays or frames placed on the seabed to guide the camera for data acquisition. Both manual mosaicing and sophisticated underwater engineering are expensive and therefore beyond the reach of the vast majority of coral reef ecologists.

Due to recent advances in technologies, the time is ripe for the application of underwater mosaics to coral reef ecology. Developments in computer vision (Gracias and Santos-Victor, 2001; Gracias et al., 2003; Pizarro and Singh, 2003; Singh et al., 2004) have freed underwater

**Underwater Landscape Mosaics, Figure 1** Underwater landscape mosaic, Carysfort Reef, Key Largo, FL. (a) Mosaic created from video images covers approximately 190 m<sup>2</sup>, with a resolution of 1.35 mm/pixel. Landscape views of meter-scale reef plots are excellent tools for tracking threatened species such as the *Acropora palmata* in this mosaic. (b) Integrated still image (10 megapixel) matched to the boxed area in (a) shows details of individual coral colonies at sub-millimeter scale resolution. (c) Algae and coral, such as the *Halimeda opuntia* and *Porites asteroides* in this enlarged view of the upper box in (b) can be identified to species. (d) Detail of the lower box in (b) showing skeletal chimneys in *Acropora* (arrows) formed as the coral tries to recover from biting by damselfish.

mosaics from the burden of being stitched together by hand. In addition, recent advances in consumer-grade electronics and optics, including cameras, housings, lights, and batteries, mean that high-quality underwater

images do not necessarily need to be acquired by expensive submersibles.

Several researchers have recognized the potential application of mosaicing technology to coral reefs and several

“strip” mosaics of coral reefs have been published (e.g., Kupfner and Lybolt, 2003; Armstrong, 2007; Camilli et al., 2007). These strip mosaics, which are created along transects, lack the spatial accuracy and spatial context of a landscape view of a reef plot (Lirman et al., 2007; Gleason et al., 2007). Other mosaicing efforts, such as by Ludvigsen et al. (2007), used a still camera with very slow frame rates for mosaic creation, necessitating the use of a 400 kg remotely operated vehicle with artificial lights as an imaging platform, and a closed-loop control system that incorporated multiple navigation technologies. Such complex imaging platforms are typically both expensive and unavailable to coral reef biologists.

### Landscape mosaic technology

Landscape mosaic technology allows users to create underwater mosaics with four appealing features for coral reef ecologists (e.g., Lirman et al., 2007). First, processing is automated, converting input video frames to an output mosaic with little to no user intervention. Second, the algorithm is camera and platform independent, requiring only images with a high degree of overlap. Third, the motion model is general enough to deal with unstructured motion including tolerance to moderate off-nadir views. Fourth, the characteristics of the resulting mosaics have been validated against diver data. Areas of  $\sim 400 \text{ m}^2$  ( $\sim 2,000$  frames) can be imaged with sub-millimeter spatial resolution (pixel size) and spatial accuracy of  $\pm 5 \text{ cm}$  (Gintert et al., 2009). Data collection time underwater is less than one hour. Highly automated mosaic production in the lab requires about four man-hours and 24–36 h computer time with current desktop processors. Mosaicing software includes modules for filtering out the effects of refracted sunlight in shallow water imagery (Gracias et al., 2008) and eliminating the visibility of seams among neighboring images in the final mosaics (Gracias et al., 2009).

### Key benefits

Landscape mosaics provide meter-scale views of plots of coral reefs that have previously been unobtainable. This enables new measures of reef health, such as documenting spatial relationships of disease patterns, or the effects of hurricane damage (Gleason et al., 2007) and ship groundings (Lirman et al., 2010). High spatial accuracy, combined with a landscape view, enables accurate size and distance measurements to be taken directly from the mosaic. Mosaics can be georeferenced and integrated with other data sets using Geographic Information Systems (GIS). Mosaics are efficient tools to track patterns of change over time. Mosaics collected in repeat surveys can be referenced to one another with only four permanent markers, allowing monitoring of individual coral colonies without the need for extensive tagging. Due to the ease of data acquisition and relatively short dive times required, landscape mosaics are also superior tools for surveys of mesophotic coral ecosystems (Gleason et al., in press).

The use of landscape mosaics can also reduce the costs of obtaining coral reef and benthic habitat data and improve the quality and archive potential of ecological data. Reduced cost of coral reef monitoring is expected because: (a) special biological training is not necessary for acquiring the imagery; (b) reduced time in the water will increase efficiency of field work, and permit monitoring of deeper sites; and (c) accurate measurement of accidental damage on reefs will minimize restoration costs. For example, effective communication with a jury in a lawsuit following a ship grounding is an example of where this technology could pay for itself. The mosaicing technology is not intended to replace direct expert observations for benthic habitat analysis, but rather mosaics add important capabilities for analyzing, storing, and sharing important time-series data for the purpose of natural resource management. Underwater mosaics both retain the strengths associated with direct expert observations and circumvent the limitations of a traditional diver-only approach.

## UNVEGETATED CAYS

---

Peter Flood  
 University of New England, Armidale, NSW, Australia

On many reef top surfaces there are accumulations of bioclastic, wave and tide transported gravel and sand sized

sediment. Usually, the gravel (shingle) material is concentrated on the windward side of the reef and is a lag deposit whereas the sand sized material is transported to the leeward side of the reef where the refracted waves cause the sediment to deposit about the nodal energy point. The shingle cays tend to remain relatively static in their location except for movement under extreme storm and cyclonic activity. The sand cays are extremely mobile and many are ephemeral. There are recorded instances where sand cays have moved a significant distance across the reef top and in some instances the sediment has been removed from the reef top completely. The previous trace of the existence of such cays is shown by the occurrences of stranded residual beachrock ridges which represent the traces of the previous beach.

The cays develop initially as intertidal banks which build up progressively to be continuously above the high tide level. Many of these cays display the evidence of initial colonization by plants including shrubs. Vegetation may come and go as the upper cay surface is swept by salt-laden moisture in wave run up and washover, especially during cyclones.

The unvegetated cay may evolve over a period of time into vegetated cay which displays serial changes in their vegetation. Such vegetation changes can be reversed by cyclonic damage to the vegetation by wave washover or storm surge.

The unvegetated cays show considerable variety in their shape, size, and orientation with respect to the reef surface. Both elongate elliptical and oval shapes are predominant and the shape usually reflects the shape of the coral reef itself.

Throughout the Great Barrier Reef Province (GBRP) the size of the cays appears to be somehow related to the time that the reef top surface has been exposed to tidal influences. Elongate elliptical and oval shapes occur usually reflecting the shape of the coral reef on which they occur. Throughout the GRBP and also elsewhere in the other reef provinces the size of the cay appears to be related to the length of time that the reef top surface has been at, or near the sea level. In the GRBP, Hopley (1982) identified four types of unvegetated cays. They are:

- (a) Linear sand cays
- (b) Linear shingle cays
- (c) Compact sand cays
- (d) Compact shingle cays

Stoddart et al. (1978) surveyed numerous compact sand cay types in the northern GRBP. Types b. and d. are relatively rare and usually they are unstable. Types, a. and c. are more common. Cays appear to be more prevalent in the inner shelf region of the GRBP, especially the northern GRBP. Unvegetated cays also occur less frequently on the outer barrier ribbon reefs and in the Swain Reef region of the GRBP, however a higher Holocene sea level or even several periods of sea level at or near modern sea level

over a period of several millennia are not a prerequisite for cay development, as coral cays are also common in other reef provinces where sea level is only just reaching current levels, e.g., Belize, Atlantic Reef Province.

The carbon dating of the sediments which constitute the unvegetated cays indicates a mid Holocene to contemporary age (Kench et al., 2005, 2009). This relatively young age is also supported by the young age of the abandoned beach rock ridges, which outline the previous positions of cays that no longer exist or which have migrated to a new position on the reef top surface.

## UPWELLING AND CORAL REEFS

Miles J. Furnas

Australian Institute of Marine Science, Townsville MC, QLD, Australia

### Definition

Upwelling: An oceanographic process where sub-surface water is transported or mixed vertically toward the surface. Upwelling systems usually refer to locations or regions where cool high-nutrient water from the thermocline or below is lifted into the surface layer or euphotic zone, stimulating enhanced biological productivity.

Coriolis force: The deflecting effect of the earth’s rotation on a moving fluid.

### Introduction

Coral reefs are the iconic benthic ecosystem of tropical seas and oceans. The warm, generally clear waters in which most coral reef systems occur are indicative of the low-nutrient (dissolved and particulate) status of these waters and the typically low level of nutrient inputs to these systems. The high productivity of coral reefs is supported by the efficient extraction of dissolved nutrients and organic matter from the very large volumes of water which flow over, around and through reefs, high rates of nitrogen fixation and rapid recycling within reefal food webs. Active reef building does not occur along tropical and subtropical coastlines characterized by strong and persistent upwelling (e.g., Peru, SW Africa), primarily due to low water temperatures (<18°C) in these areas which are below optimal for coral reef growth.

Upwelling occurs when subsurface water moves vertically to replace overlying water which is displaced laterally by a forcing process, usually wind stress on the surface water. Vertical water velocities associated with upwelling are much slower than ocean currents. Horizontal water velocities in ocean currents typically range between  $10^{-1}$  and  $10^2$  cm s<sup>-1</sup>. Average vertical velocities due to upwelling are on the order of  $10^{-4}$  and  $10^{-2}$  cm s<sup>-1</sup>. Upwelling is important in the ecology of the oceans because it returns deep water to the surface. The upwelled water often contains higher concentrations of nutrients which support enhanced phytoplankton production, and in turn, higher levels of herbivores and carnivores: zooplankton, squid, fish, birds, marine mammals.

A close examination of regional coral reef ecosystems indicates that upwelling occurs in many of these systems. The nature of this upwelling differs in a number of ways from upwelling in the larger eastern boundary current and equatorial oceanic divergence zones. Coral reefs can develop where upwelling is less intense or intermittent. The upwelled water rarely reaches the surface to produce the cool surface plumes found in the eastern boundary

current systems (e.g., California, Peru). Rather, the upwelled water is mixed into the low-nutrient surface layer, producing a more diffuse regional enrichment of surface waters. The upwelled nutrients stimulate production of phytoplankton and organic matter in the mixed layer which contributes to regional food chains. Very little of the upwelled nutrients directly impinge on the reefs, and then usually only upon the deeper subsurface part of the reef.

## Upwelling systems and coral reefs

### Topographic upwelling

Currents flowing over and around irregular bathymetry such as seamounts, islands and platform reefs form turbulent boundary zones and 3-dimensional wakes. When surface waters around reefs are drawn into the general flow of the current past a reef, subsurface waters can be upwelled to replace them. One example is the seaward margin of the far-northern Great Barrier Reef (12°S) where a shelfbreak current flows northward past a series of invaginated bays or indentations in the steep shelfbreak reefs. Shoaling of the thermocline has been observed in these invaginations (Thomson and Wolanski, 1984). The shoaling thermocline is characterized by the uplift of the subsurface chlorophyll maximum into the euphotic zone and higher rates of primary production. In shallow continental shelf waters, localized upwelling occurs in eddies formed behind reefs, islands and shoals (Liston et al., 1992).

### Intrusive upwelling

Intrusive upwelling occurs where oceanographic processes raise the oceanic thermocline above the depth of the shelfbreak. The cool, nutrient-enriched waters of the thermocline can then move laterally as a bottom-hugging layer (Andrews and Furnas, 1986). Subsequent mixing on the shelf due to wind stress or turbulence around bathymetry disperses water and nutrients from this layer into the surface layer. Upward movement of the thermocline at the shelfbreak can be caused by a variety of processes, including the offshore displacement of shelf waters by Ekman wind stress which thins the surface layer, uplift of the thermocline in response to geostrophic pressure gradients in ocean currents running along the shelfbreak, internal tides, shelf-waves, or meanders in the shelfbreak current system. Intrusive upwelling associated with boundary currents is known to occur in the central and southern Great Barrier Reef (East Australian Current), on the Campeche Bank, Mexico (Yucatan Current), and along southern and eastern Florida (Gulf Stream).

The timing and extent of intrusive upwelling is variable. Upwelling into the Great Barrier Reef is seasonal, with virtually all occurring during the summer months (October–April). Individual upwelling events (Figure 1) can last for a few days to several weeks. Short-lived events are restricted to the outer continental shelf while episodic large events occurring every few years can extend nearly

across the continental shelf and displace up to one-third of shelf waters (Furnas and Mitchell, 1996). Little is known regarding seasonal or event-coupled variability in Yucatan Current upwelling. During the intrusion events, a bottom layer of Yucatan Channel thermocline water can extend across the Campeche Banks (Furnas and Smayda, 1987). Similar intrusions from the Gulf Stream also occur in the Florida Keys (Leichter et al., 1996) and along the eastern coast of Florida (Atkinson et al., 1978).

The velocity of the shelfbreak boundary current is a major factor influencing intrusive upwelling. Stronger flows are coupled to greater geostrophic tilt of the thermocline. When the thermocline is elevated along the shelfbreak, short-lived shelfbreak events related to internal waves or tides (Leichter et al., 1996) are also more likely to occur.

### Internal waves

Rhythmic vertical oscillations of subsurface density gradients (internal waves) occur frequently in the ocean. Internal waves are most noticeable at the boundary between the warm (low-density, low-nutrient) surface mixed layer and the thermocline. Internal waves have amplitudes ranging from tens to hundreds of meters and can travel thousands of kilometers across or around ocean basins.

Where the surface layer is relatively thin (<100 m), vertical water movements in internal waves can lift nutrient-enriched thermocline waters and subsurface chlorophyll higher into the euphotic zone where phytoplankton are at least briefly exposed to higher light levels. In situations where the thermocline is shallow enough or waves are large enough, the uplifted high-nutrient thermocline waters can inundate the lower parts of coral reefs with high-nutrient water (Leichter et al., 1998, 2003).

Internal wave interactions with reefs are known from oceanic islands in the Pacific Ocean (Tahiti, Palau; Wolanski and Delesalle, 1995; Wolanski et al., 2004), the Indian Ocean (Scott Reef; Wolanski and Deleersnijder, 1998) and the seaward margin of the Great Barrier Reef (Myrmidon Reef; Wolanski and Pickard, 1983). Where the water movements associated with internal waves interact with local bathymetry, regular vertical density structures can be disrupted, stimulating vertical mixing or transport of nutrients or plankton up the reef slope and into the mixed layer (Leichter et al., 1998).

### Ekman upwelling

Winds blowing over the ocean surface push surface waters downwind. The Coriolis force induced by the rotation of the earth simultaneously deflects the moving water to the right (Northern Hemisphere) or left (Southern Hemisphere). Where winds blow parallel to a coastline and the surface waters are displaced away from the coast, subsurface waters upwell into the surface layer to replace the displaced water. When the upwelled water comes from the thermocline or below, the cooler upwelled water contains higher levels of nutrients which supports higher biological

**Upwelling and Coral Reefs, Figure 1** (Top) Cross-shelf section of water temperature through a cold-water intrusion into Palm Passage, central Great Barrier Reef (18.5°S) in October, 1987. (Bottom) Concurrent distributions of nitrate in water samples collected on the outer shelf.

productivity. In regions where upwelling is strong and persistent (western North and South America, western North Africa, Namibia) reef growth is inhibited by lower temperatures ( $<18^{\circ}\text{C}$ ) of upwelled water. In some tropical and subtropical locations, however, upwelling-favorable winds are seasonal and warm surface water temperatures persist for much of the year. Examples of intermittent-upwelling systems include the Gulf of Panama (Glynn and Stewart, 1973) and Oman (Glynn, 1993). Wind regimes in these systems are monsoonal with seasonal changes in wind direction that blow surface waters onshore and offshore.

In contrast to South America and South Africa, corals and coral reefs occur along the western side of Australia despite the presence of upwelling-favorable winds for much of the year. Corals are able to grow because upwelling of sub-thermocline water is suppressed by the southward-flowing Leeuwin Current. This current transports warm, low-density water from the Timor Sea southward along the coast. The surface cap of low-density water generally prevents cooler, high-nutrient water from reaching the surface. Wind-forced upwelling does occur, but the upwelled water comes from the low-nutrient

surface layer. A small amount of upwelling of cooler, deeper water occurs episodically along the front of Ningaloo Reef (20°S). Productivity in waters adjoining Ningaloo Reef is higher during El Niño events when flow in the Leeuwin Current is weakened, thinning the surface layer and allowing more deep waters to be mixed into the euphotic zone (Furnas, 2007).

Ekman upwelling also occurs in the equatorial Pacific Ocean where persistent easterly trade winds blow north and south of the equator. Ekman forcing causes surface waters to move away from the equator, creating a divergence zone. The displaced surface waters are replaced by doming subsurface waters along the equator. A number of island systems with coral reefs (Galapagos Islands, Canton Island, e.g., Smith and Jokiel, 1975) are located within the zone of equatorial divergence and resulting high surface-nutrient levels.

### Upwelling and reefal food webs

Upwelling plays an important role in the nutrient biogeochemistry and ecology of the oceans as upwelling returns nutrients to the well-lit surface layer. Regions of active and

persistent upwelling are typically highly productive, both in terms of phytoplankton and higher trophic levels: zooplankton, squid, fish, birds, marine mammals (Ryther, 1969). The high upwelling rates in the major upwelling zones along the eastern margins of ocean basins result in regional water temperatures which are too low for coral growth and reef development.

Coral reefs occur in a number of systems which are subject to either intermittent upwelling or are characterized by hydrographic conditions that largely prevent cold upwelled water from reaching surface-living reefs. The upwelled water is mixed into the surface layer, producing a more diffuse low-level enrichment that supports higher productivity of regional food chains (Furnas, 2007). This productivity produces plankton and particulate organic matter which is accessible to reefal filter and detrital feeders (Hamner et al., 1988). Very little of the upwelled nutrients directly impinge on near-surface reef communities (Andrews and Muller, 1983) to be taken up by benthic algae (free-living and symbiotic).

## Summary

Several types of upwelling processes contribute to the productivity of coral reef systems through low-level or intermittent nutrient enrichment of regional ecosystems without pronounced lowering of water temperatures. Coral reef growth is inhibited in regions of strong and persistent upwelling by suboptimal ( $<18^{\circ}\text{C}$ ) water temperatures. The nutrients introduced by upwelling stimulate regional productivity, which in turn produces plankton and particulate organic matter accessible to reefal detritus and plankton feeders.

## URANIUM SERIES DATING

Jian-xin Zhao<sup>1</sup>, Lindsay B. Collins<sup>2</sup>

<sup>1</sup>University of Queensland, Brisbane, QLD, Australia

<sup>2</sup>Curtin University of Technology, Perth, WA, Australia

## Synonyms

U-series dating; U-series disequilibrium dating

## Definition

Uranium series: The radioactive decay series that starts with  $^{238}\text{U}$ ,  $^{235}\text{U}$  and  $^{232}\text{Th}$  and ends with stable isotopes of  $^{206}\text{Pb}$ ,  $^{207}\text{Pb}$  and  $^{208}\text{Pb}$ , respectively.

**Secular equilibrium:** A situation in which the quantity of a radioactive isotope remains constant because its production rate (due to decay of a parent isotope) is equal to its decay rate. Secular equilibrium can only occur in a radioactive decay chain if the half-life of the daughter radioisotope is much shorter than the half-life of the parent radioisotope, as typical of the uranium series decay chains.

**Uranium series disequilibrium:** Unequal radioactivity of the intermediate radioisotopes (e.g.,  $^{234}\text{U}$ ,  $^{230}\text{Th}$ ,  $^{226}\text{Ra}$ ) in the U-series decay chains resulting from changes in the respective elemental ratios (or called elemental fractionation) during a geological or environmental event or process. Once disequilibrium occurs, secular equilibrium status will be restored, or in other words, disequilibrium will be reduced to below analytical detection levels, after a period of time, e.g., 5–7 times of the half-life of  $^{230}\text{Th}$  for the  $^{234}\text{U}$ – $^{230}\text{Th}$  disequilibrium.

**Uranium series dating:** A radiometric dating technique is commonly used to determine the age of uranium-rich, mainly carbonate, materials such as speleothem, coral, fossil bone materials, etc. Unlike a U–Pb or Rb–Sr age that is determined by the accumulation of a stable daughter isotope, a U-series age is calculated based on the measurements of the level or degree to radioactive disequilibrium between the parental and daughter radioisotopes (e.g.,  $^{234}\text{U}$  and  $^{230}\text{Th}$ ) within a sample.

## Introduction to uranium series and uranium series dating

$^{238}\text{U}$ ,  $^{235}\text{U}$  and  $^{232}\text{Th}$  (with half-lives of 4.5, 0.7 and 14 billion years, respectively) decay to stable  $^{206}\text{Pb}$ ,  $^{207}\text{Pb}$  and  $^{208}\text{Pb}$ , through the emission of 8, 7 and 6  $\alpha$  particles, and many intermediate  $\beta$  and  $\gamma$  reactions, respectively (see, Ivanovich and Harmon, 1992). The three decay chains involve a total of ten elements (U, Pr, Th, Ac, Ra, Rn, Po, Bi, Pb, and Tl) and 39 isotopes. Half-lives of the 33 intermediate short-lived radioisotopes in these decay chains range from fractions of a second (e.g., for  $^{216}\text{Po}$ ) to 245,000 years (kyr) (e.g., for  $^{234}\text{U}$ ). As such, the uranium series dating technique relies on the decay of these long-lived radioactive uranium and thorium isotopes into a series of unstable, short-lived radioactive “daughter” isotopes. It dates the “event” or “process” that causes elemental or isotopic fractionation leading to radioactive disequilibrium among the intermediate short-lived radioisotopes. As the majority of these short-lived radioisotopes have half-lives ranging from a few hundred thousand years down to only a few years, the method provides a dating range for the different uranium series of a few thousand years to 500,000 years (i.e., seven half-lives of  $^{230}\text{Th}$ ). Uranium series have been used to date uranium-rich mineral deposits, deep-sea sediments, shells, bones, and teeth, and to calculate the ages of ancient lake beds.

Among a large number of the intermediate parent–daughter disequilibria, only the  $^{238}\text{U}$ – $^{234}\text{U}$ – $^{230}\text{Th}$  disequilibrium is most commonly used for palaeoenvironmental applications, such as dating reef corals

and speleothems. The companion low-abundance  $^{235}\text{U}$  to  $^{207}\text{Pb}$  decay chain via  $^{231}\text{Pa}$  (half-life, 32.7 kyr) is seldom used, because Pa occurs in large quantities only in uranium ores; its geochemical characteristics are difficult to determine, and its measurement is analytically challenging. Nevertheless,  $^{235}\text{U}$ – $^{231}\text{Pa}$  disequilibrium has found some applications in coral dating and palaeoceanography, especially for assessment of the coral age reliability in combination with the  $^{234}\text{U}$ – $^{230}\text{Th}$  disequilibrium (Edwards et al., 1997).

## $^{238}\text{U}$ – $^{234}\text{U}$ – $^{230}\text{Th}$ disequilibrium dating or U–Th dating: theoretical principle

Here, only  $^{238}\text{U}$ – $^{234}\text{U}$ – $^{230}\text{Th}$  disequilibrium dating [also commonly described in literature as Uranium–thorium (U–Th) dating, Thorium-230 dating,  $^{238}\text{U}$ – $^{234}\text{U}$ – $^{230}\text{Th}$  disequilibrium dating,  $^{238}\text{U}$ – $^{230}\text{Th}$  disequilibrium dating, U-series disequilibrium dating and U-series dating], which is most relevant to coral reef studies, will be described in detail.

As described above, the U–Th dating method is based on the decay of  $^{238}\text{U}$  (with a half-life  $T_{1/2} = 4.469 \times 10^9$  years) to stable  $^{206}\text{Pb}$  via intermediate daughters such as  $^{234}\text{U}$  ( $T_{1/2} \sim 245,000$  years) and  $^{230}\text{Th}$  ( $T_{1/2} \sim 75,400$  years). In this decay series,  $^{238}\text{U}$ – $^{234}\text{U}$ – $^{230}\text{Th}$  disequilibrium occurs when U is differentiated from Th during a particular geological or environmental event or process. In the case of natural aqueous systems, for example, in which U is slightly soluble, but Th is highly insoluble, carbonate precipitated from the aqueous system will contain trace amounts of U (usually 0.01–100 ppm), but virtually no Th, leading to excess U in the decay chain (that is,  $^{238}\text{U}$  and  $^{234}\text{U}$  activities  $\gg$   $^{230}\text{Th}$  activity). Once this radioactive disequilibrium is established, it takes about seven times the half-life of  $^{230}\text{Th}$  ( $\sim 500$  kyr) for the system to return to near secular equilibrium, or to the level where the degree of disequilibrium is below the limit of detection by thermal ionization mass spectrometry (TIMS) or inductively-coupled plasma mass spectrometry (ICP-MS). The application of  $^{238}\text{U}$ – $^{234}\text{U}$ – $^{230}\text{Th}$  systematics allows accurate age determinations spanning the last 500,000 years, covering  $\sim$ seven times the half-life of  $^{230}\text{Th}$ . For samples that contain U and small to negligible amount of Th, the ages are determined from the following simplified equation (modified after Edwards et al. (1987a) :

$$1 - \left( \frac{^{230}\text{Th}}{^{238}\text{U}} \right) = e^{-\lambda_{230}T} - \left[ \left( \frac{^{234}\text{U}}{^{238}\text{U}} \right) - 1 \right] \times \left( \frac{\lambda_{230}}{\lambda_{230} - \lambda_{234}} \right) \left( 1 - e^{(\lambda_{234} - \lambda_{230})T} \right),$$

where  $(^{230}\text{Th}/^{238}\text{U})$  and  $(^{234}\text{U}/^{238}\text{U})$  are the measured activity ratios, and  $\lambda_{230}$  and  $\lambda_{234}$  are the decay constants of  $^{230}\text{Th}$  and  $^{234}\text{U}$ , respectively, and  $T$  is the age of the sample, which can be worked out iteratively.

The validity of the age calculated from the above equation relies on a number of assumptions: (1) the U–Th

isotopic systematics remain closed since the formation of the dated material or, in other words, since the U/Th fractionation event; (2) the generation of the dated material is a fast process relative to the time elapsed since, so that this process can be considered as a U/Th fractionation “event;” and (3) the dated material does not contain any initial inherited  $^{230}\text{Th}$  at the time of formation, or this initial  $^{230}\text{Th}$  is small or precisely known and can be corrected for. The correction of initial or non-radiogenic  $^{230}\text{Th}$  is based on the measurement of  $^{232}\text{Th}$  presented in the sample and the assumption of initial  $^{230}\text{Th}/^{232}\text{Th}$  ratio. Usually, a bulk Earth  $^{230}\text{Th}/^{232}\text{Th}$  ratio of  $4.4 \times 10^{-6}$  with arbitrarily assigned 50% is used for correction and this assumption holds in most cases (Shen et al., 2008). However, recent studies show that such ratios may vary dramatically in some corals and speleothems (Beck et al., 2001; Cobb et al., 2003; Hellstrom, 2006), and thus site-specific initial ratio measurement is needed for high-precision dating especially for very young corals (Shen et al., 2008; Yu et al., 2006).

### U-Th dating: analytical methods

Bateman (1910) first proposed that the U-series can be used for dating. Khlapin (1926) first applied the U-series to dating uranium-rich minerals (e.g., uraninite) assuming that these minerals do not contain initial Th and  $^{238}\text{U}$  and  $^{234}\text{U}$  are in secular equilibrium. Barnes et al. (1956) first applied the  $\alpha$ -counting method to dating corals. Chen et al. (1986) performed the first precise analysis on  $^{234}\text{U}$  in seawater using TIMS. Edwards et al. (1987a) made the first  $^{230}\text{Th}$  measurements in corals by TIMS. Luo et al. (1997) first used multi-collector ICP-MS to measure U and Th isotopes.

The  $\alpha$ -counting method, or called alpha spectrometry, is based on measuring  $\alpha$  particles of specific energy emitted from U and Th isotopes of a sample. The mass spectrometry techniques directly measure U and Th isotope ratios in a sample. Prior to alpha- or mass- spectrometry measurements, the sample is dissolved and doped with a tracer or called spike consisting of a mixture of artificially enriched  $^{229}\text{Th}$  (or  $^{228}\text{Th}$ ) and  $^{233}\text{U}$  (and/or  $^{236}\text{U}$ ) with known concentrations. Then, U and Th in the sample are pre-concentrated, separated and purified using established chemical procedures including ion exchange chromatography. Through measuring the mixed isotope ratios by alpha or mass spectrometry, U and Th concentrations and isotope ratios in the sample are calculated and then the sample age worked out using the above equation.

Comparing with  $\alpha$ -counting, the mass spectrometry U–Th dating techniques offered great improvements in precision with an order of magnitude reduction in sample size and measurement time. There are now three different mass spectrometry techniques that are in common use for U-series dating: thermal ionisation (TIMS) (Edwards et al., 1987a), inductively coupled plasma (ICP) ionisation using a sector magnet and a single collector system (SC-ICP-MS) (Shen et al., 2002), and ICP ionisation using

a sector magnet and a multi-collector system (MC-ICP-MS) (Luo et al., 1997). In all instruments, the radioisotopes of interest are ionised, separated according to mass and detected using either Faraday collectors or ion counters in analog or ion-counting mode. ICP-based systems achieve nearly complete ionisation of all elements and have orders of magnitude better sensitivity than TIMS systems for U and Th which both have high ionisation potential. However, sampling of the plasma by the mass spectrometer is only about 1% efficient, and instrumental mass-dependant isotope fractionation affects ICP-based systems an order of magnitude more strongly than TIMS. Because of this, MC-ICP-MS offers only a moderate advantage over TIMS, and TIMS analysis is expected to find continued use for some time into the future. MC-ICP-MS is clearly superior to TIMS in sample throughput (e.g., Hellstrom, 2003) and in achieving high-precision dating for samples beyond 300 kyr because Th mass fractionation can be monitored and corrected (Stirling et al., 2001). TIMS is still more commonly used in dating extremely young carbonates, especially corals (e.g., <1,000 years) (Zhao et al., 2009, for review).

In addition, the development of laser ablation techniques allows in situ U–Th analysis of uranium-rich samples to be performed on the MC-ICP-MS, offering new dimensions of applications (Eggins et al., 2005; Potter et al., 2005; Stirling et al., 2000). More recently, an order of magnitude improvement in precisions was achieved on the MC-ICP-MS by measuring all the isotope signals on Faraday collectors with high concentrations of U and Th, enabling coral and speleothem samples of more than 300 kyr to be precisely dated (Andersen et al., 2004).

### U-Th dating: applications

Since the development of mass spectrometry techniques over 20 years ago, U–Th dating has found widespread applications in the fields of geological, environmental and archaeological sciences, revolutionized Quaternary research. Comprehensive descriptions of the techniques and major applications can be found in key text books such as Ivanovich and Harmon (1992) and Bourdon et al. (2003) and some review articles (Edwards et al., 2003; Goldstein and Stirling, 2003; McDermott, 2004; Schwarcz, 2002; van Calsteren and Thomas, 2006; Zhao et al., 2009). The applications of U–Th dating to coral reef studies are discussed in detail in a great volume of literature (e.g., Bard et al., 1990a,b, 1996; Chen et al., 1991; Edwards et al., 1987a,b; Potter et al., 2005; Scholz and Mangini, 2007; Shen et al., 2008; Stirling et al., 1998; Thompson and Goldstein, 2005). Examples of important outcomes from such studies include accurate calibration of  $^{14}\text{C}$  timescale beyond the range of dendrochronology (Bard et al., 1990b; Schramm et al., 2000; Beck et al., 2001), precise timing and characterisation of glacial–interglacial cycles up to 500 kyr BP (Winograd et al., 1992, 1997), establishment of the duration of the last interglacial sea-level high stands (Edwards et al., 1997;

Henderson and Slowey, 2000; Stirling et al., 1995, 1998), characterisation of sea-level fluctuations during the last glacial–interglacial cycles (Bard et al., 1990a; Chappell et al., 1996; Esat et al., 1999), recognition of leads and lags in global climatic oscillations and sea surface temperature changes (Beck et al., 1997), and dating and characterisation of global monsoon variability and calibration of the Greenland ice core chronology (Wang et al., 2001, 2004, 2005, 2008; Yuan et al., 2004).

### Introduction

Vanuatu is an archipelago located in the South-West Pacific (Figure 1) composed of numerous volcanic islands. These islands are part of the Vanuatu island arc located at the convergent boundary of the Australian and Pacific tectonic plates (Figure 1). The central part of this island arc is characterized by the absence of a physiographic trench because of the subduction of morphological features from the d'Entrecasteaux zone and by the unusual proximity of the island of Espiritu Santo and Malakula close to the plate boundary. Moreover, the islands are surrounded by modern reefs and most of them are characterized by emerged reefs (Figure 2) and a series of raised coral terraces. The Holocene uplift rate of the islands of the central part reaches up to  $5.5 \text{ mm} \cdot \text{year}^{-1}$  in the southwest of Espiritu Santo and up to  $3.4 \text{ mm} \cdot \text{year}^{-1}$  in the north of Malakula (Taylor et al., 1980, 1987). The occurrence of three parallel chains, viz., the western chain (Espiritu Santo and Malakula), the central chain (active volcanoes of Aoba and Ambrym) and the eastern chain (Maewo and Pentecost), is also uncommon as noted by Mitchell and Warden (1971). The distribution and consequently the extension of modern reefs depend on the tectonic history and the sea-level variations.

### The modern reefs

Although little is known regarding the morphology and biology of the Vanuatu reefs, some studies were previously performed. Guilcher (1974) analyzed the structure and defined different types of reefs comprising the fringing and open-sea reefs. In 1990, Veron identified 62 genera

and about 296 species of reef corals and Done and Navin (1990) defined different and typical shallow water habitats of many coral reefs around several islands. This last study revealed differences in the zonation of assemblages between exposed and sheltered reefs. In the outer reef slopes, the biological communities are characterized on the reef crests by abundant coralline algae and robust-branching corals (mainly *Acropora* spp. and pocilloporids) and in the reef slopes by massive and branching corals. The open embayments are characterized by massive domal *Porites* spp. accompanied by *Acropora* spp. while the sheltered embayments by soft corals sometimes with domal *Porites* spp. and various branching forms of corals.

### Neotectonics and sea-level variations

Coral reefs can be used as recorders of neotectonic movements and paleosea level (Figures 2 and 3) as reported by the numerous works performed on the raised reef terraces from Vanuatu by Mitchell (1968), Neef and Veeh (1977), Jouannic et al. (1980, 1982) and Taylor et al. (1980). Moreover, all these works show the broad potential of this area to analyze in detail the Late Quaternary sea-level variations. In Vaté, identification of sea levels from the last 125 ka (1 ka = 1,000 years) was performed by Neef and Veeh (1977). In Malakula, previous surveys identified six main terraces in the North West culminating up to 350 m (Mitchell, 1968; Jouannic et al., 1980). More recent U/Th coral dating of a series of raised terraces provides sea-level estimates of the marine isotopic stage (MIS) 3 and several higher relative sea levels were identified from 55 to 40 ka (Cabioch and Ayliffe, 2001). North of Malakula, the island of Espiritu Santo is characterized by a series of raised terraces in the east and south and on islands off the south coast including Aoré, Malo, Araki, Tangoa and Urélapa Islands (Jouannic et al., 1980; Taylor et al., 1980, 1985, 1987, 2005). The altitude of coral terraces increases to the west indicating a tilting to the east.

**Vanuatu, Figure 1** (a) the South-West Pacific showing the plate boundary and the location of the Vanuatu archipelago. AUS: Australia; PNG: Papua New Guinea; S: Solomon Islands; NHT: New Hebrides (Vanuatu) Trench. (b) location of the coring sites in the island of Espiritu Santo at Tasmaloum and Urélapa.

Coral dating in terraces and cores performed in the sites of Tasmaloum and Urélapa (Figure 1) shows the occurrence of a Late Quaternary cycle of uplift and subsidence in Espiritu Santo over one or two hundred thousand years

(Taylor et al., 2005). This cycle can be explained by the subduction of morphological features on the D'Entrecasteaux Zone on the converging Australian plate (Figure 1).

**Vanuatu, Figure 2** Example of emerged reefs in Vanuatu because of the uplifting (photo G. Cabioch/IRD).

**Vanuatu, Figure 4** Emerged Holocene coral on an uplifted reef (photo G. Cabioch/IRD).

**Vanuatu, Figure 3** Modern corals observed just below the sea surface (photo G. Cabioch/IRD).

In addition at the scale of the Holocene, modern emerged corals and reefs (Figures 2 and 4) were used to analyze the recent vertical motions especially to estimate the uplift rate and the seismic recurrence intervals and the timing of aseismic subduction in the central part of Vanuatu (Taylor et al., 1980, 1985, 1987, 1990).

### Paleoclimatology

Corals from Vanuatu offer the opportunity to study the climatology of the past using the isotopic analyses and/or trace element measurements. The variations of isotopes and trace elements (Sr/Ca, U/Ca) document the variations of the past sea surface temperatures (SST) and sea surface salinities (SSS). In 1997, the analyses of *Porites* corals collected in cores from Espiritu Santo by Beck et al., and dated at 4228, 9550, 9731 and 10344 year BP, indicate SST close to present for the 4,228-year-old *Porites*, and 5–7°C cooler

prior to that time for the others. This work was one of the first studies related to the evolution of the SST during the last deglacial sea-level rise. Parallel to such studies, Vanuatu, south of the West Pacific Warm Pool, is located in a region affected by the climatic interannual variations due to the El Niño Southern Oscillation (ENSO) phenomenon and the Vanuatu can be considered as a key region to analyze its frequency and intensity using coral analyses. In this region, the fluctuation of the south branch of the Intertropical Convergence Zone, the South Pacific Convergence Zone, is marked by variations in the oceanographic parameters. Several works were devoted to this topic. The  $\delta^{18}\text{O}$  analyses of a 173-year-old coral by Quinn et al. (1996) document the climatic variability at Espiritu Santo. These analyses show the combined effects of SST variations and rainfall (SSS changes). In 2004, Kilbourne et al. evaluated various methods to reconstruct the SSS in Espiritu Santo on a *Porites* coral and concluded that combining  $\delta^{18}\text{O}$  and Sr/Ca measurements is a reliable tool to reconstruct the SSS. In 2000, Corrège et al. measured the SST in a 47-year-old *Porites* coral dated at 4,166 cal year BP. Comparison between the SST from this fossil coral and the modern instrumental SST revealed cooling anomalies of SST, interpreted as reflecting more intense El Niño events (see entry *El Niño, La Niña, and ENSO*) and a stronger interannual variability at this period. In 2004, Corrège et al. analyzed a *Diploastrea* coral from the Younger Dryas providing data on this peculiar period.

### Radiocarbon calibration and reservoir ages

The corals from Vanuatu appear to be of broad interest to contribute for the extension of the radiocarbon calibration curve and the knowledge of the reservoir ages. In 1998, Burr et al. performed both radiocarbon and  $^{230}\text{Th}$  analyses for  $^{14}\text{C}$  calibration with decadal resolution on a *Diploastrea heliopora* coral from the Younger Dryas (between 11.7 and

12.4 cal ka BP.) of Espiritu Santo. The data show sporadic rapid increase in the  $\Delta^{14}\text{C}$  in relation with the climatic changes during this period of the Younger Dryas. In 2004, Cutler et al. calibrated radiocarbon dates (between 8 and 23 ka) with  $^{230}\text{Th}$  and  $^{231}\text{Pa}$  measurements performed on the corals of Espiritu Santo. Then, in 2005 Chiu et al. (2005) performed high-paired  $^{230}\text{Th}/^{234}\text{U}/^{238}\text{U}$  and  $^{14}\text{C}$  measurements on corals from Araki island extending the calibration curve from 12 to 50 ka. Taking into account these results, a statistical model was proposed to estimate the conversion of ages obtained using radiocarbon into calendar years. More recently, a work dedicated to the analysis of the reservoir ages from the Younger Dryas, covering 700 years, showed that the average was larger than today and a reservoir age variability on a decadal timescale (Burr et al., 2009).

### Reef development during the last 24 ka of the deglacial sea-level rise

Several coring operations were performed in the uplifted reefs of 2 areas of Espiritu Santo at Tasmaloum and Urélapa (Figure 1) characterized by uplift rates of about  $5.5 \text{ mm}\cdot\text{year}^{-1}$  and  $3 \text{ mm}\cdot\text{year}^{-1}$ , respectively (Taylor et al., 1980). At Tasmaloum, several episodes of development can be observed from 24 to 15 ka with fine skeletal detrital facies and robust-branching corals, then from 15 to 10 ka with dominant robust branching coral assemblage indicating another shallowing up sequence and from 10 to 6 ka, a mixture of robust branching coral and foliaceous coral assemblages typical of deeper waters, probably reworked. Moreover, microbialite crusts can be observed from 20 to 6 ka, and particularly abundant from 16 to 10 ka (Cabioch et al., 1998). At Urélapa, a small uplifted island, the reef development is characterized by two episodes well marked by the composition of corallgal assemblages. The first episode, from 23 to 11.5 ka, is characterized by assemblages characteristic of medium to high energy conditions close to the sea surface (keep-up mode) while the second episode from 11.5 to 6 ka by corallgal assemblages of relatively deeper habitats from 10 to 20 m. The succession of these two episodes of corallgal assemblages from a keep-up growth to a catch-up growth mode  $\sim 11.5$  ka probably indicates global plaeoceanographic changes (Cabioch et al., 2003). Such studies show that the analyses of corallgal biofacies provide useful information to analyze the history of the reef development and to examine the role of global (or regional) oceanographic factors and tectonic parameters on reef growth.

### Summary

The distribution of coral reefs of the Vanuatu archipelago and the occurrence of coral terraces depends on the tectonic factor in this area of island arc. Nevertheless, the reef development, although disturbed by this factor, appears to be controlled by global climatic factors. This is well illustrated by the occurrence of growth mode change at  $\sim 11.5$  ka. The occurrence of successive coral terraces is also under the control of the eustatic sea-level variation in combination

with the vertical motions. The climatic context of the region of Vanuatu, located in the zone of fluctuation of the SPCZ is of broad importance. Consequently, high monthly resolution geochemical analyses of corals provide information on past SST and SSS giving data on the past ENSO phenomenon.

## VAUGHAN, THOMAS WAYLAND (1870–1952)

---

Robert N. Ginsburg  
 University of Miami RSMAS/MGG, Miami, FL, USA

Thomas Wayland Vaughan (1870–1952) was a pioneering paleontologist who made major contributions to the systematics and ecology of living and fossil corals, to coral reefs, larger foraminifera and Tertiary stratigraphy of Florida and the entire West Indies.

As a youngster during the turn of the century in a small East Texas town, he collected fossil plant impressions. That interest in paleontology flowered later as a student at Harvard where he became interested in fossil corals. After a year of studying specimens in Europe's museums he began what was to be a thorough characterization of the Tertiary and living corals of the Americas. His first publication in 1900 was a landmark monograph on Eocene and Lower Oligocene corals of the United States that established him as an authority on the systematics of hexacorals. Next, he shifted emphasis to a study of extant corals of Hawaii and Laysan. By 1907 he had completed the first comprehensive analysis of that fauna, a publication that is notable for its assembly of all available ecological data. The many questions raised by his works on coral skeletons, made Vaughan realize that the answers could only come from a study of living corals.

Beginning in 1907 and for more than a decade he spent parts of every summer researching living corals mostly at the Carnegie Institute's Tortugas Marine Laboratory on remote Loggerhead Key some sixty miles west of Key West, Florida. There he began summer research on the ecology of corals and on the coral reefs of Florida and the Bahamas. Among his accomplishments were the first systematic data on growth rate of reef-building corals of the Tropical North Atlantic, the ecology of coral reefs in Florida and the Bahamas and much more. During the rest of the years from his base in Washington he led the exploration of the Cenozoic geology of Florida and eventually of most of the islands of the West Indies and the Panama.

Always quick to publish his findings, Vaughan produced dozens of substantial works on the geological history of corals and coral reef limestones. In addition he authored seminal works on calcareous sediments and the first geological history of southern Florida. Vaughan's final contribution to the coral literature was his collaboration with John Wells that produced a still-consulted 1949 monograph on corals of the tropical Atlantic.

At the age of 52 he shifted his scientific interests to the larger foraminifera and became a leader in that specialty just as he had done for corals and coral reefs. After 30 years as a member of the United States Geological Survey, he left in 1924 to be Director of the Scripps Institution for Biological Research. For the next dozen years he led the development of Scripps' graduate training and its expansion into oceanographic research. For much of that period he also chaired two influential committees one on international Pacific oceanography and the other on submarine configuration of the oceans. Oriental art was one of his several avocations and late in his life he was in great demand as a lecturer on that subject.

## VEGETATED CAYS

David Hopley<sup>1</sup>, Harold Heatwole<sup>2</sup>

<sup>1</sup>James Cook University, Townsville, QLD, Australia

<sup>2</sup>North Carolina State University, Raleigh, NC, USA

Transformation of an unvegetated cay into a vegetated form depends to a large extent on stability, which in turn is a reflection of size and shape (Aston, 1995), availability of a source of water (a permanent water table is associated with cays with a minimum width of 300 m) and a source of viable seeds (via flotsam or from bird droppings). Large oval islands are the most stable with linear islands, often with highly mobile spits and large outcrops of beach rock, the least stable. Cemented deposits, especially beach rock, can form quickly and any erosion or movement of the island results in outcrops on the beach or even isolated on the reef flat. Also forming on cays on which significant numbers of birds nest is phosphatic cay sandstone formed by interaction of bird droppings or guano with the mineral substrate. Whilst beach rock is normally intertidal, the phosphate may be precipitated at the domed surface of the water table internally within the island, (Hopley, 1997; Hopley et al., 2007).

Even densely vegetated cays can be unstable and there are examples on the Great Barrier Reef (GBR) of vegetated cays disappearing completely (see Hopley et al., 2007). Changes can be brought about by storms or changing wind patterns (Flood, 1986), changes to sediment budgets or anthropogenic impacts. Erosion can expose mature soils and late successional stages of vegetation behind the beach, whilst the addition of new sediments will result in colonising vegetation being added at later stages.

Whilst colonising vegetation can be added to an unvegetated cay relatively quickly, the climax vegetation (e.g., *Pisonia* forest) with mature organic soils may take several 1,000 years to form. However, even in areas of the world where the relative sea level has been at or close to its present position for >6,000 years it is important to remember that mature coral cays were almost certainly non-existent during the Holocene transgression, significant for the birds and turtles which now use them as nesting sites. Vegetated cays also serve as roosting sites on bird migration routes and as sources of nutrients leached from guano and from rich organic soils, thereby enhancing algal growth on the reef flat (Chen and Krol, 1997). Vegetated coral cays are an integral part of reef-flat ecology but have a dubious future in the face of rising sea levels and modified sediment budgets produced by global climatic change.

## VOLCANIC DISTURBANCES AND CORAL REEFS

Peter Houk

Pacific Marine Resources Institute, Inc., Saipan, MP, USA

## Definition

Volcanic eruptions refer to the release of volcanic ash and magma to the atmosphere and surrounding waters containing coral reefs.

## Introduction

Volcanoes have been emphasized in coral reef studies since Charles Darwin first formalized his thoughts surrounding the creation of tropical islands and atolls (Figure 1, Darwin, 1842). Volcanic activity is arguably the most influential natural disturbance that impacts reef growth and modern coral assemblages. However, its frequency of occurrence is much lower than other natural disturbances such as climate-induced bleaching and tropical cyclones. Physically, eruptions deliver hot magma that forms igneous rock of varying composition (Le Bas and Streckeisen, 1991), as well as volcanic ash, to the nearshore waters. Both can smother vast expanses of living coral reefs rapidly (Pandolfi et al., 2006), but longer-lasting, secondary impacts also exist. Volcanic ash particles contain numerous minerals in high concentrations that influence surrounding waters; most notably iron, magnesium, and silica (Flaathen and Gislason, 2007). Minerals from volcanic ash provide a pulse of key limiting ingredients that facilitate the rapid growth of phytoplankton, translating to enriched productivity of surface waters, often at the scale of entire oceanographic regions (Uematsu et al., 2004). These plankton blooms eventually die and decay, releasing nutrients and bacteria as they sink. Corals cannot uptake all of these available nutrients as fast as macroalgae, so following major volcanic ash input,

**Volcanic Disturbances and Coral Reefs, Figure 1** Anatahan, Commonwealth of the Northern Mariana Islands, following a 2003 eruption that provided no lava flow but lots of volcanic ash to surrounding waters.

patches of macroalgae and cyanobacteria growth often emerge on the surrounding coral reefs. Even when the volcanic activity has ceased, re-suspension of volcanic ash during large-wave events can continue to facilitate this cycle, as well as increase turbidity levels and reduce the penetration of sunlight for substantial periods of time.

### Reef growth

It has long been recognized that igneous rock created from magma differs in porosity and permeability (Davis, 1969), and thus will provide for differential connectivity with island aquifer systems. Houk and Starmer (2010) show that the remote volcanic Mariana Islands, Western Pacific Ocean, have strikingly different (up to 1 part per thousand) ambient salinity levels, attributed to differential igneous rock porosity and permeability. In turn, this creates selective environmental conditions favorable for algae and sponge growth where low salinity exists, and increased coral growth where salinity is higher (Figure 2). The former yield low-rugosity reef structures with little three-dimensionality through time, while the latter provides for high-relief primary coral framework development. Clearly, volcanic bedrock is not all the same and differing characteristics have consequences for reef growth over time.

### Modern assemblages

Due to its rarity and unpredictable timing, relatively few studies have examined the impacts of volcanic activity upon reefs and subsequent recovery. Studies have shown that while lava flows are detrimental to living reef communities, regrowth of vibrant coral assemblages can occur within 5 years in Indonesia (Tomascik et al., 1996). In Hawaii, where wave exposure and seasonal temperature variation are much higher, studies suggest a much longer time period may be required for modern coral growth to return, up to 50 years (Grigg and Maragos, 1974). A 2003 eruption of Anatahan, Mariana Islands, yielded no lava flow but large quantities of volcanic ash that smothered most of the surrounding reef (Figure 1, Houk and Starmer, 2010).

**Volcanic Disturbances and Coral Reefs, Figure 2** Growth of modern assemblages on coral reefs surrounding volcanic islands strongly differs depending upon the characteristics of igneous rock. High-porosity bedrock has high connectivity with the islands aquifer and provides for continuous algae growth over time and low three-dimensionality of reef structure (a), compared with low-porosity systems (b).

Here, environmental conditions are similar to Hawaii and wind-generated waves often re-suspend volcanic ash, thus selecting against rapid coral settlement and growth. Predictions using other islands that have been erupting at varying times throughout the past 100 years revealed that ~90 years is estimated for coral abundance and species richness recovery to expected levels at the entire island scale.

## VOLCANIC LOADING AND ISOSTASY

---

Kurt Lambeck  
 Australian National University, Canberra, ACT, Australia

The Earth's mechanical response to changes in surface loading is usually described in terms of local or regional isostasy in which the load is supported to varying degrees by the strength of the crust or lithosphere and by the reaction of the underlying mantle to the deformation of this layer.

For a general formulation for this response see Chapter *Glacio-Hydro Isostasy* and the response to volcanic loading can be seen as a special case of this. The essential differences between the two cases are (1) the timescale of loading is usually much longer than that of the glacial cycles, (2) the length scale of the loads are shorter than that of the large ice sheets, (3) the load-stress magnitude of the volcanic load may be much larger than that of ice loads and (4) the volumes of the volcanic loads are comparatively small such that when the volcanoes form in an ocean environment the water displaced and the concomitant hydro-isostasy can usually be ignored.

The formation of large volcanic complexes usually occurs over periods of a million years or longer. This is greater than the typical relaxation time of the mantle inferred from the glacio-hydro isostatic analyses such that the mantle can usually be considered as a fluid of zero viscosity. However, the loading time is likely to be comparable to the relaxation times of the lithosphere, particularly for the lower lithosphere, such that the viscosity structure of the lithosphere may be important. The smaller length scale of the volcanic loads and the unimportance of the hydro-isostatic loading means that the isostatic models need not be global and flat-earth representations are usually adequate. But, combined with the load-stress magnitudes being generally larger, it also means that the structure of the crust and the lithospheric part of the mantle may also be important in determining the isostatic response. The larger load stresses also mean that elastic failure of the crust may occur. Another difference between the two loading problems is that the process of volcanic loading itself may have a modifying effect on lithospheric properties because of heat transport into the lithosphere during the active phase of loading.

The isostatic response to volcanic (and sediment) loads can be qualitatively represented by the regional isostatic model in which the stress-bearing layer overlies a fluid mantle of zero viscosity. Usually, this layer will have depth-dependent physical properties but for computational convenience any lateral variability is usually ignored. The time history of loading is also mostly ignored. [Figure 1](#) illustrates the schematic elastic response for a disk-shaped load for which there exist convenient analytical solutions (such solutions also exist for other axially symmetries such as parabolic profile loads). The deformation beneath the load is characterized by a “flexural parameter” or “radius of relative stiffness,”  $l$ , defined as

$$l^4 = D/(\rho_m - \rho_l)g$$

$D$  is the flexural rigidity and for a depth ( $z$ ) dependence of elastic parameters (shear modulus  $\mu$  and bulk modulus  $K$  with  $\lambda = K - (2\mu/3)$ ) where the integration is across the elastic layer from its upper surface  $z = +H/2$  to its lower surface  $z = -H/2$ . For typical elastic parameter values,  $l \approx 50$  km and much of the spatial variation in the deformation occurs over a distance of about  $4l$ .

**Volcanic Loading and Isostasy, Figure 1** Deflection of an elastic plate of flexural rigidity  $D$  overlying a zero viscosity fluid, subject to a disk load of variable radius  $A$ , density  $2.8 \text{ gm/cm}^3$  and height  $5 \text{ km}$ . The moat forming at the edge of the load is assumed to be filled in with material of the same density up to the level of the undeformed surface consistent with the definition of  $D$  used here. From Lambeck and Nakiboglu (1980).

Once the load radius exceeds about  $3-4l$ , the displacement beneath the center of the load approaches that of local isostatic compensation (see Chapter *Glacio-Hydro Isostasy*) with a maximum displacement of  $z_{\text{max}} \approx -(\rho_l/\rho_m)h$  where  $h$  and  $\rho_l$  are the height and density of the load ( $h$  is measured with respect to the undeformed surface). Solutions (1, 2) in Figure 1, with a load radius of up to about  $100 \text{ km}$ , are representative of single volcanic complexes, whereas the larger diameter loads are more representative of basaltic plateau or large sedimentary loads. The solutions for large radius begin to resemble the surface deflection across continental margins from melt-water loading in the glacio-hydro isostatic problem.

Normally, a broad trough develops around the load down to a maximum depth of  $z \approx 0.5z_{\text{max}}$  that can be expected to be partly filled as part of the volcanic complex and partly by water if the formation is in an ocean environment. This is seen around some of the large volcanic complexes such as the Hawaiian chain. Thus, in more realistic models the question of how this moat is filled must be considered. Beyond the moat, a small uplifted bulge occurs on the order of some tens of meters in peak amplitude and typically  $100-150 \text{ km}$  in width (Figure 2), with the actual dimensions being a function of the lithospheric parameters, load dimensions and the degree to which the moat has been filled.

If a viscous component is introduced to describe stress relaxation in the lithosphere, particularly in the lower part of this layer, then the sea floor subsides until the local isostatic limit is approached and the outer bulge migrates inwards.

Observational evidence that supports these models of regional compensation or lithospheric flexure comes from gravity (including geoid), seismology and sea-level

**Volcanic Loading and Isostasy, Figure 2** Uplift of the peripheral bulge for the disk load of  $60 \text{ km}$  radius. From Lambeck (1981).

investigations. The seismological evidence includes mapping of the slope of seismic reflectors within the crust beneath the load and moat and variations in the depth of the Moho. The seismic data can also define some of the internal crustal structure beneath the volcano and establish whether faulting has occurred as a result of loading. Gravimetric and geoid surveys indicate positive anomalies over seamounts and volcanoes that are consistent with the mass distribution within the regional compensation models and permit the flexural parameters to be estimated. Primary outcome of such studies include estimates of the effective elastic thickness of the lithosphere, the dependence of  $D$  on the age of the lithosphere at the time of volcanic seamount formation, and evidence for relaxation of the load stress for the larger volcanic

loads. These estimates of the effective elastic thickness are generally significantly less than the estimates from hydro-isostatic analyses, indicating that stress relaxation occurs in the lower lithosphere on timescales between the glacial cycles and volcanic loading and longer. The sea-level data point to the uplift of atolls and other islands positioned on the peripheral bulge. This appears, for example, to have been the case for Henderson Island that was uplifted as a result of the formation of the Pitcairn volcanic complex at  $\sim 0.8$  million years ago. Another example is the island of Makatea which was probably uplifted during the formation of the Tahiti volcanic complex.

## WALTHER, JOHANNES (1860–1937)

---

Eberhard Gischler  
Institut fuer Geowissenschaften, Frankfurt am Main,  
Germany

Johannes Walther was one of the founders of sedimentology and paleoecology (Middleton, 1973; Seibold, 1992; Ginsburg et al., 1994), and conducted four fundamental studies on modern coral reefs (Walther, 1885, 1888, 1891, 1910). Walther was born on 20 July 1860 in Thuringia, Germany. He studied geology and biology at the University of Jena, where his mentor was the famous biologist Ernst Haeckel. Walther completed his Ph.D. in 1886. Subsequently, he studied modern algal reefs in the

Mediterranean and fossil reefs in the Tertiary of Sicily and in the Triassic of the Austrian Calcareous Alps (Walther, 1885). He was among the first who recognized the significance of calcareous algae as reef builders. Based on his studies in the modern reefs, and using thin-section and chemical analyses, he attempted to explain the textures he found in the fossil reef limestones. In his work on the coral reefs of the Sinai Peninsula, Walther (1888) was able to study modern and elevated subfossil reefs nearby. The latter offered three-dimensional sections, which led Walther to the conclusions that only 40% of a reef is formed by coral framework and that 60% is made of detritus filling the interstices. Furthermore, he realized the importance of antecedent topography for reef development and distribution. Walther (1891) established his findings when studying modern and subfossil reefs between India and Ceylon. Again, he stressed the importance of detritus in reefs and the fact that a great part of this material is produced by the destructive activity of organisms. Also, he considered changes in relative sea-level, when discussing subfossil reef terraces. In 1890, Walther became a Professor at the University in Jena. From 1906 to 1928, he held the chair of geology and paleontology at the University of Halle. He returned to the algal reefs in the Mediterranean in 1910 and found significant facies changes that had occurred over the past 25 years, geologically a very short time period. In 1914, Walther was able to visit the Great Barrier Reef of Australia, but he had to return home early due to the outbreak of WW I. Unlike other reef researchers during that time period, Walther did not contribute to the coral reef problem, i.e., the interpretation of shallow atolls and barrier reefs in oceanic settings in the light of Darwin's (1842) subsidence theory. Even so, he was among the first to recognize the importance of calcareous algae for reef-building, described what is today called bioerosion, in great detail, hinted to the significance of loose sediment

in modern reefs, and elaborated the meaning of antecedent topography for reef development. Walther died on 4 May 1937 in Hofgastein, Austria.

## WAVE SET-UP

Michael R. Gourlay  
 The University of Queensland, Brisbane, QLD, Australia

### Definitions

**Wave run-up.** The vertical distance between the ocean (tide) level and the maximum height reached by the uprush of waves breaking on a beach or structure.

**Wave set-up and set-down:** Positive and negative changes in mean water level produced as waves shoal and break on beaches and reefs.

**Wave thrust:** A vertically integrated force per unit wave crest length produced by changes in wave momentum as waves propagate in shoaling and shallow water. It has two components; an isotropic pressure and a unidirectional force in the direction of wave propagation. Also known as radiation stress.

**Shoaling.** The process by which the wave height, length, celerity and other properties of the waves change as they travel from deep(er) water into shallow(er) water.

See also Chapter [Waves and Wave-Driven Currents](#) for definitions of other terms concerning waves.

Mathematical symbols are defined where they first appear in the text, or on a relevant figure. The subscript *o* refers to the deep water values of the various quantities.

### Introduction

In the late 1940s, it was observed at Bikini Atoll that the predominant 12–15 s swell waves breaking on the reef caused a significant inflow of ocean water into the atoll lagoon. The accompanying increase in water level in the lagoon, known as wave set-up, was 0.45–0.6 m (Munk and Sargent, 1954; Von Arx, 1954). As the significance of waves as a dominating agent in determining reef-top morphology and ecology was increasingly recognized in the late 1970s and the 1980s, it became apparent that wave set-up plays a significant role in defining wave-driven current systems on coral reefs (e.g., Roberts, 1981; Hearn et al., 1986). (see Chapter [Waves and Wave-Driven Currents](#)).

Wave set-up is also an important factor, particularly in microtidal environments, in determining groundwater levels in beaches on coral cays or other reef-protected shorelines. These wave-induced groundwater levels influence the formation of *Beach Rock*, as well as the success of turtle nesting behind the beach. Wave set-up and associated wave run-up also have been identified as important factors in causing flooding of low-lying reef-protected coasts and reef islands (see Chapter [Infrastructure and Reef Islands](#)).

### Wave set-up on beaches

A wave train propagating onto a beach or reef produces changes in mean pressure within the water and a unidirectional force in the direction of wave propagation (Longuet-Higgins and Stewart, 1964). This wave thrust increases as the water depth decreases. On a beach offshore of the breaker zone, if it is assumed that there is no frictional dissipation at the bottom, the increasing wave thrust is balanced by a change in mean hydrostatic pressure such that the mean water level decreases as the waves propagate shoreward, that is, wave set-down occurs. Within the surf zone where energy is being dissipated by wave breaking, the wave thrust decreases as the breaking surge travels shoreward and consequently the mean water level rises, that is, wave set-up occurs ([Figure 1a](#)).

[Figure 1a](#) shows the occurrence of wave set-down and set-up on a relatively steep beach. The still water level (s.w.l.) is the water level if there were no waves present and is the reference level for measuring set-down and set-up. In an oceanic situation the s.w.l. will vary with the tides and meteorological influences such as storm surge. The changes in mean water level (m.w.l.) occur when waves approach, shoal, break and run up the beach. The m.w.l. can not be seen but it can be measured either as the time-averaged mean position of the water level at any specific location approaching and within the surf zone or

**Wave Set-Up, Figure 1** Wave set-up on beaches. (a) Waves breaking on a steep, plane beach. (b) Waves breaking on a beach with offshore bar.

as the mean hydrostatic pressure on the bottom at that location. Maximum set-down  $\bar{\eta}_b$  occurs in the vicinity of the break point; the maximum set-up  $\bar{\eta}_m$  occurs where the m.w.l. intersects the beach face. However, measurements of set-up in the swash zone are not always reliable and there are differences of opinion as to their meaning (Gourlay, 1992). Some researchers prefer to refer to the set-up measured at the location where the s.w.l. intersects the beach profile (Dean and Walton, 2009).

If it is assumed that the height of the breaking surge is a constant fraction  $\gamma$  of the actual water depth  $d$  (including set-up  $\bar{\eta}$ , i.e.,  $d = \bar{\eta} + h$ ) in the surf zone, the theory of Bowen et al. (1968) predicts that the ratio of the m.w.l. slope in the surf zone  $\tan \beta$  to the beach slope  $\tan \alpha$  is a simple function of  $\gamma$ , that is,

$$\tan \beta / \tan \alpha = K = 1 / \left( 1 + \frac{8}{3\gamma^2} \right)$$

Laboratory experiments (Bowen et al., 1968) confirmed the existence of set-down and set-up on plane beaches. Subsequent analysis of a wide range of laboratory data for impermeable plane beaches suggested that the maximum set-up on fairly steep beaches ( $\tan \alpha \leq 0.1$ ) is about 30% of the initial breaker height  $H_b$ , whereas for flat beaches ( $\tan \alpha \leq 0.04$ ) it is only 15% of it (Gourlay, 1992). For comparison, wave set-down probably would be no more than 5% of the breaker height.

Nielsen (1988) measured wave set-up on a beach at Dee Why, NSW, which has a relatively steep face and an offshore bar. There were different set-up profiles for small and large waves. Small waves broke directly on the beach face creating a steep m.w.l. gradient shoreward of the initial breakpoint. Large waves broke on the offshore bar or flatter portions of the profile. In this case, the m.w.l. had two distinct gradients, a flat one in the outer surf zone and a steeper one following a second break point inshore on the beach face (Figure 1b). These experiments also revealed that, even if there were no rainfall, the groundwater level behind the beach is elevated above the ocean tide level. This groundwater level varies with changes both in the height of the waves and in tide levels. Laboratory experiments on wave-formed beaches (Gourlay, 1992) indicated wave set-up profiles for large and small waves similar in general form to those observed by Nielsen. They also showed that, for steep beaches, the wave set-up and hence the wave-induced groundwater level were larger for beaches formed of fine sand in comparison with those formed of medium sand or fine pebbles (see discussion below). Recent analyses of various field data indicate that the set-up at the still water line is about 20% of the significant wave height  $H_{os}$  with a variation of about  $\pm 10\%$  (Dean and Walton, 2009).

Set-up  $\bar{\eta}_m$  should not be confused with run-up  $R_u$ . The latter term refers to the maximum vertical height on the beach reached by the swash/uprush from the breaking

waves. Run-up is commonly measured relative to s.w.l. on beaches and engineering structures but this may not be appropriate for reef-protected beaches (see discussion below). For a plane beach or structure, the run-up is related to the wave conditions and beach slope by the following equation:

$$\frac{R_u}{T\sqrt{gH}} = C \tan \alpha$$

where the parameter  $C$  ( $\leq 1$ ) varies with the roughness and permeability of the beach (see Nielsen, 2009).

### Wave set-up on coral reefs

Wave set-up on reefs is governed by the same theoretical principles as wave set-up on beaches. However, there are some differences in approach because the morphology of reefs is different from that of beaches. In general, the profile of a reef will have a reef face of variable slope, a reef crest/rim, and a reef flat and/or lagoon. In the case of a fringing reef or cay on a platform reef, normally there will be a relatively steep beach at the far side of the reef flat (Figure 2). With a platform reef or atoll lagoon, there will be a leeward reef rim or reef.

When the reef face is not too steep ( $\tan \alpha < 0.1$ ) and the waves break on it, the theory of Bowen et al. (1968) for set-up on a plane beach has been applied by Tait (1972)

to give an estimate of wave set-up on a horizontal reef top. As reef faces are generally much rougher than sandy beach profiles, bottom friction may be significant and probably will reduce the wave height and hence the wave thrust sufficiently to eliminate any wave set-down on the reef face prior to breaking. With this assumption, the wave set-up  $\bar{\eta}_r$  on a horizontal reef is given by  $\bar{\eta}_r = K(h_b - h_r)$  (Figure 2a). The set-up is maximum when  $h_r = 0$ , i.e., when the tide level is equal to the reef top level, and it reduces to zero when  $h_r \geq h_b$ , i.e., when waves pass over the reef without breaking.

During the period between 1980 and 1996, several researchers measured wave set-up on laboratory models of coral reefs with widely varying profiles (Gourlay, 1996a,b). Reef-face slopes varied from greater than 1 in 50 to vertical. One model reproduced a platform reef with flow across it, whereas all the others were fringing reefs with horizontal or very flat reef tops; one of these latter had a shallow lagoon between the reef crest and the beach behind the reef. Two models involved experiments with irregular waves as well as regular ones. In only one case was any attempt made to measure the wave set-up on the actual reef in the field.

In general, these laboratory experiments indicate that wave set-up on a quasi horizontal reef increases with both increasing ocean wave height and wave period and decreasing water depth over the reef top. No wave set-up

Wave Set-Up, Figure 2 Wave set-up on coral reefs. (a) Waves breaking on reef face. (b) Waves breaking at reef edge.

occurs if the water depth is large enough for the waves to pass over the reef without breaking. This situation occurs when the deep water ocean wave height  $H_o$  is less than  $0.4 h_r$ . For steep-faced reefs, waves which just pass over the reef edge may break on the reef top, whereas larger waves will break at the reef edge.

For waves breaking on the top of a steep-faced reef (Figure 2b), a theoretical analysis using wave thrust theory predicted that the set-up on a horizontal reef is about 14% of the ocean wave height (Gourlay, 1996a). This is close to the maximum set-up on a flat beach.

For flatter reef faces (Figure 2a), larger waves break on the reef face seaward of the reef crest and in some cases dissipate significant energy before the broken waves reach the reef crest. In these latter situations, wave set-up on the reef top approaches a limiting value with increasing wave height. Furthermore, the magnitude of the set-up on the reef top decreases as the slope of the reef face decreases. Analysis of experimental data for both steep and flatter reef faces shows that wave set-up on the reef top increases with increasing  $H_o^2 T$ , which quantity is proportional to the ocean wave power or energy flux (Gourlay, 1996b) (see Chapter *Waves and Wave-Driven Currents*).

Munk and Sargent (1954) first suggested a possible relationship between wave set-up on coral reefs and ocean wave power. Gourlay (1996b) applied this principle to waves breaking at the edge of a steep-faced horizontal reef. This analysis produced a relationship for wave set-up on a steep-faced horizontal reef which reduces to the following form:

$$\bar{\eta}_r = \frac{0.015 K_p g^{1/2} H_o^2 T}{d_r^{3/2}} \left[ 1 - 0.16 \left( \frac{d_r}{H_o} \right)^2 \right]$$

where the reef profile factor  $K_p$  ( $\leq 1$ ) varies with the reef face slope  $\tan \alpha$  and  $d_r$  is the water depth, including wave set-up, on the reef top. Ocean waves are variable in height and period and are commonly represented by the significant wave height  $H_{os}$ . In calculating wave set-up on a reef,  $H_o$  in the above formula is the height of a regular sinusoidal wave, which is equivalent to the root-mean-square wave height  $H_{orms}$  ( $= \frac{H_{os}}{\sqrt{2}}$ ) of irregular ocean waves (see Chapter *Waves and Wave-Driven Currents*).

Numerical models which reproduce wave transformation and breaking on flatter but still relatively steep reef faces have been developed by other researchers. Both Skotner and Apelt (1999) and Massel and Gourlay (2000) have computed wave set-up values which agree reasonably well with those measured on laboratory models with different reef face slopes and profiles.

Irregular ocean waves tend to occur in groups of larger waves followed by groups of smaller waves. These groups of larger waves pump water onto the reef top or lagoon, increasing the set-up above its mean value but the following groups of smaller waves are unable to sustain this higher water level and water flows back seawards over the reef rim reducing the set-up below the mean value.

Hence, the wave groups create a dynamic component of wave set-up which is superimposed upon the steady wave set-up calculated using  $H_{orms}$ .

The magnitude of the dynamic set-up or surf beat depends upon the width of the reef. The wider the reef the greater its capacity to absorb and smooth out the fluctuations in set-up resulting from the wave groups. On the other hand, the dynamic set-up fluctuations decrease in magnitude as the water depth over the reef crest decreases, even though the magnitude of the steady wave set-up increases with decreasing water depth. Hence, surf beat will be more significant at high tide than low tide and at high spring tides than neap tides (Seelig, 1983; Gourlay, 1996b).

In certain situations, resonant surf beat oscillations may be instigated by the coincidence of the wave group period with the natural period of oscillation of the water body on the reef flat. Substantial amplification of the surf beat at the shoreline and consequent severe erosion or damage to shore facilities is possible (Nakasa and Hino, 1990).

Recent laboratory and numerical modeling studies on the same reef profile as used in Seelig's experiments show clearly the influence of surf beat (infragravity waves) in producing resonant set-up oscillations on a narrow coral reef. Such oscillations dominate the run-up on a reef-protected beach (Nwogu and Demirbilek, 2009). Field observations following Typhoon Rus at Guam in 1991 found an inverse relationship between reef flat width and overwash height (run-up). That is, the highest overwash occurred along steep coasts adjacent to narrow reef flats where the contribution of waves to overwash was greatest (Jaffe and Richmond, 1993).

Various theoretical and empirical formulae representing the processes just described have been utilized for calculating estimates of the wave set-up on a coral reef and the conditions under which a reef-top island is likely to be flooded during an extreme event (Gourlay, 1996b; 1997). After an allowance has been made for storm surge, these calculations initially determine the set-up resulting from waves breaking on the reef rim and then consider the influence of the surf beat upon water levels in the lagoon. Calculation of the wave run-up on the beach, relative to the m. w. l. on the reef top, gives another estimate of the waves' flooding potential for a specific situation. Such calculations clearly show both the protective action of coral reefs in reducing the size of waves breaking on reef island beaches and the potential for wave set-up to raise reef-top water levels significantly higher than high tide level and hence flood reef islands during extreme events.

To determine the wave-induced groundwater level  $\bar{\eta}_g$  behind the beach (Figure 3), it is necessary to calculate the wave set-up caused by the residual waves breaking on the relatively steep plane reef island beach for the appropriate ocean tide plus set-up water level on the reef top in front of the beach. At the time of writing, there is no simple way for calculating the wave set-up in a permeable beach of a particular sand size, let alone for a permeable beach comprised of a wide range of materials, such as is frequently found on reef island beaches. However, advanced numerical modelling simulating the

**Wave Set-Up, Figure 3** Wave set-up, wave run-up and wave-induced groundwater for a reef top beach.

interaction between waves and beach groundwater has produced encouraging results when compared with experimental laboratory data for a beach of a homogeneous sand (Ang et al., 2004). The ground water level behind a reef island beach will also be affected by changing tide levels on the reef flat, as well as rainfall on the island.

### Measurements of wave set-up on coral reefs

There have been very few actual measurements of wave set-up on coral reefs. Apart from situations where set-up caused by swells from distant storms or hurricanes has resulted in flooding or damage to infrastructure on reef islands (Gourlay, 1996b; Amanaki et al., 2003), the most complete set of field data of wave set-up across a reef flat has been obtained by Jago et al. (2006) at Lady Elliot Island, the southernmost reef in the Great Barrier Reef region. These measurements were made with simple slow response stilling wells and measuring techniques similar to those developed by Nielsen (1999) for measuring wave set-up on beaches. Waves and mean water levels were measured over both rising and falling tides during low to moderate wave conditions ( $H_{os} < 0.5$  m). Both wind waves and swell were present. The spring and neap tidal ranges at this site are 1.7 m and 0.9 m, respectively. The set-up was observed to vary both spatially and temporally across the reef with changing water depth. At low tide, both wind waves and swell broke on the reef edge generating set-up on the reef flat. At midtide, set-up occurred both at the reef edge, where wind waves broke, and on the island's beach, where the swell broke. At high tide, no waves broke at the reef edge and there was negligible set-up there but significant set-up occurred on the beach, where both wind waves and swell broke. Set-down also was observed both on the reef face before waves broke on the reef edge and on the reef flat as waves passed over the reef rim into deeper water on the reef flat.

Recent measurements of wave set-up and wave-driven currents in an atoll lagoon in the Cook Islands have shown that wave pumping drives the flushing of these lagoons

when there are no deep passages or gaps in their surrounding reef (see Chapter *Waves and Wave-Driven Currents*).

### Summary

Waves breaking on a reef or beach create an increase in m.w.l. in the surf zone called wave set-up. This set-up increases with increasing height and period of the ocean waves and decreases with increasing water depth over the reef, becoming negligible when waves pass over the reef without breaking. Maximum set-up occurs when the ocean water (tide) level is about the same level as the reef top. The water level differences caused by wave set-up drive reef-top current systems and the flushing on many atoll lagoons. Wave set-up may contribute significantly to the groundwater elevation in cays and the sedimentary margins of continental islands. Wave set-up caused by both local storm waves and swells from distant storms may cause significant flooding, erosion and damage on reef islands, particularly where resonant oscillations occur on a reef top.

## WAVE SHOALING AND REFRACTION

Michael R. Gourlay

The University of Queensland, Brisbane, QLD, Australia

### Definitions

**Diffraction.** The process by which wave energy is transmitted laterally along a wave crest into a sheltered zone. Most commonly observed behind breakwaters, small islands and exposed reefs which create a sheltered zone behind them.

**Orthogonal.** A line at right angles to the wave crest indicating the direction of travel of the wave. Also known as wave ray.

**Refraction.** (1) The process by which the direction of a wave moving in shallow water at an angle to the bottom contours is changed; the part of the wave crest advancing in shallower water moves more slowly than the part of the crest still advancing in deeper water. (2) The bending of wave crests by currents.

**Shoaling.** The process by which the wave height, length, celerity and other properties of the waves change as they travel from deep(er) water to shallow(er) water.

See also *Waves and Wave-Driven Currents* for definitions of other terms concerning waves.

Mathematical symbols are defined where they first appear in the text, or in a relevant figure. The subscript *o* refers to the deep water values of the various quantities.

### Introduction

When ocean waves propagate around or onto coral reefs, their characteristics change as they interact with the changing seabed morphology. The resulting changes in wave height and direction determine when and where waves break and the patterns of wave crests and wave-driven currents that develop on a given reef.

### Shoaling of waves

The shoaling process occurs as waves approach a straight beach or reef face with their crests parallel to the bottom contours. As waves propagate from deep water into water of decreasing depth *h*, both their celerity *C* and length *L* decrease (see *Waves and Wave-Driven Currents*). The wave height *H* also changes, eventually becoming increasingly larger until the waves break.

In the simple case of swell propagating from deep water into shallow water with no reflection and no dissipation of wave energy, energy conservation requires that the wave power remains constant (see *Waves and Wave-Driven Currents*). Using these assumptions with small amplitude (sinusoidal) wave theory gives the following relationship for the variation of wave height as a wave train propagates shoreward toward a beach or over a gently sloping reef face.

$$\frac{H}{H_o} = \frac{C_o}{2nC} = K_s$$

where  $K_s$  is the shoaling coefficient and  $n = C_g/C$ , where  $C_g$  is the group velocity. The parameter  $n$  varies with the relative depth  $h/L$  or  $h/L_0$ .

In shallow water, where  $C = \sqrt{gh}$ ,

$$K_s = \left( \frac{8\pi h}{L_0} \right)^{-\frac{1}{4}}$$

Finite amplitude (cnoidal) wave theory indicates that the shoaling in reality is accentuated as the ocean wave steepness  $H_0/L_0$  increases and is much more pronounced than predicted by small amplitude theory (Figure 1). Hence, the latter does not adequately predict wave heights prior to the occurrence of wave breaking, which will occur in shallow water when  $H/h$  approaches 0.8.

### Refraction of waves

In shoaling water when the wave crests cross the depth contours at an angle  $\theta$ , that part of the wave crest which first reaches a given water depth is slowed down relative to the rest of the crest and the wave crest becomes curved. The wave direction is changed and the crests tend to become parallel with the depth contours (Figure 2). For example, when long-crested waves of constant period cross a simple straight step from depth  $h_1$  into shallower depth  $h_2$  (Figure 3) simple geometry leads to the result  $\sin \theta_2 / \sin \theta_1 = C_2 / C_1$  or  $\sin \theta / C$  is a constant. This is the well-known Snell's Law, which also governs the refraction of light at the boundary between two materials with different refractive indices.

Refraction not only causes the wave crests to bend as the wave direction changes but the spacing  $b$  between the orthogonals also changes (Figure 2). When waves approach a straight plane beach at an angle, the spacing between orthogonals increases and hence the wave height reduces. Assuming that the wave energy between orthogonals remains constant, this change in wave height is

given by the refraction coefficient  $K_R = \sqrt{(b_0/b)}$  and is additional to that caused by shoaling. Hence, the wave height in shallow water is given by  $H/H_0 = K_R K_s$ .

Refraction thus results in an additional change in wave height over and above that which occurs due to the direct shoaling effect. In general, a decrease in spacing of the orthogonals represents an increase in wave height while an increase in orthogonal spacing represents a decrease in wave height. This results in wave energy being either concentrated behind submarine ridges and on headlands or dispersed behind submarine canyons and in bays. Submerged shoals and reefs usually focus wave energy behind them (Figure 4).

Where orthogonals intersect, as in Figure 4b, the simple theory breaks down. Two new processes come into play. Firstly, when there is a large change of wave height along a short length of wave crest, energy will be transferred laterally along the crest by the process known as diffraction which will tend to reduce the concentrating effect of refraction. Furthermore, as the concentrated waves travel into increasingly shallow water they will deform and eventually break, dissipating a significant amount of their energy. Where waves break at an angle to the shoreline, alongshore currents will be generated (see *Waves and Wave-Driven Currents*).

Formerly, wave refraction diagrams, showing the effect of natural bottom topography in changing wave directions and heights within a particular area, were produced manually using graphical procedures. These diagrams are now produced with digital computers using numerical modeling techniques, based upon the differential equation relating the bending of an orthogonal to the change in wave celerity (see Dean and Dalrymple, 1991).

### Refraction of waves by currents

The previous discussion of wave refraction assumes that the only movement of the water is that caused by the

**Wave Shoaling and Refraction, Figure 1** Comparison between shoaling coefficients according to small amplitude (sinusoidal) and finite amplitude (cnoidal) wave theories (from Svendsen and Brink-Kjaer, 1973).

**Wave Shoaling and Refraction, Figure 2** Wave refraction when waves approach a plane beach travelling from deep water into shallow water.

waves and that refraction is caused by changes in wave celerity as waves cross the bottom contours at an angle. However, if there are tidal currents, wind- or wave-driven currents or flow from a river mouth or a stormwater outlet, then the waves will be affected by those currents. If the waves are travelling in the same direction as the current, then their celerity will increase and they will become longer and flatter. If the waves are travelling in the direction opposite to the current, their celerity will decrease and they will become shorter and steeper and breaking may occur earlier than when no current is present. If waves cross a region where the current velocity varies in the horizontal plane, refraction will occur as the wave crests bend under the influence of the different current velocities (Nielsen, 2009).

### Wave refraction around reefs

Wave refraction around small platform reefs is an essential process in the formation of many reef-top islands. In the simplified examples shown (Figure 5), deep water ocean waves are refracted at the vertical reef face where the wave direction changes abruptly in accordance with Snell's law. They then propagate on the reef top as shallow water waves. If the waves are large enough to break on the reef rim, they will generate an alongshore current flowing along the reef rim toward the leeward end of the reef platform.

Essentially, the reef acts as a lens focussing the wave energy. If the energy is focussed off the reef, i.e., similarly to Figure 4b, then it is not possible for a cay to form on that reef. However, if the shape and orientation of a reef are favorable, the energy will be focussed on the reef platform toward its leeward side (Figure 5a). Stable cays form when the long axis of the reef lens is aligned with the dominant wave direction and the refraction pattern also does not change much with changing ocean wave direction or period. However, it is virtually impossible for a stable cay to form on a circular reef (Figure 5b), since changes

**Wave Shoaling and Refraction, Figure 3** Refraction of waves at a step in bottom elevation – derivation of Snell's Law.  $\delta t$  is the time interval during which a wave crest between two orthogonals completes its crossing of the step.

in wave direction and wave period will change the location of the focal zone. Other nonelongated reefs with sharp corners may experience significant changes in the refraction patterns and hence cay locations change when the dominant waves change direction (Figure 6a and b) (see *Infrastructure and Reef Islands*, Figure 9, for the consequences of this cay location change).

Wave interference zones (intersecting orthogonals) also may occur on small reef platforms (Figure 5a). These are generally located on the windward end of the reef platform as waves from either side of the windward end are refracted toward each other. The larger waves breaking on the windward end of the reef are able to move larger detrital material which, if present in sufficient quantities, will form a shingle bank, possibly with a T-shaped head, which in turn may develop into a windward shingle cay.

**Wave Shoaling and Refraction, Figure 4** Refraction of waves at different coastal features. (a) Concentration and dispersion of wave energy along an irregular shoreline. (b) Focussing of wave energy behind a submerged shoal.

**Wave Shoaling and Refraction, Figure 5** Wave refraction on simple reef platforms – effect of reef shape on the formation of cays. Wave period 8 s; reef top water depth 2 m; only every fifth wave crest is shown on reef top (from Gourlay, 1988).

All these processes can be seen in a drawing derived from an aerial photograph of Raine Reef in the outer northern Great Barrier Reef (Figure 7). The axis of this reef is aligned in the NW/WNW – ESE/SE direction which corresponds with the dominant southeasterly trade winds. Water depths around this reef are 200–300 m, so the ocean waves are deep water ones. On this occasion, 9 May 1963, the ocean waves were approaching from the east-northeast. These waves were travelling around both sides of the reef platform, intersecting in deep water behind the reef as both wave trains were diffracted into the sheltered zone there. When the wave crests reached the reef edge, they refracted in the very shallow water on the reef top, changing direction significantly particularly along the southern edge of the reef. After breaking on the reef rim they reformed with much shorter wave lengths and travelled across the reef crest onto the reef flat. Under these typical conditions, an interference zone occurs at the eastern end of the reef but no significant

shingle bank has yet formed there on this reef. However, there is a definite focal zone at the western end of the reef and the large stable cay, Raine Island, is located there. Its shoreline is generally aligned with the refracted wave crests, although there is evidence that these waves might be causing some easterly alongshore sediment movement on the northeastern shoreline of the cay and hence, if this persisted, would reshape the eastern end of the cay. In this case, local shoreline realignment is constrained by beach rock outcrops.

### Summary

The processes of wave shoaling and refraction change the height and direction of waves as they interact with reefs of various shapes and sizes. Significant refraction can occur along the reef edge/rim of an elongated reef aligned with the direction of the approaching ocean waves. As waves break on the reef rim, alongshore currents will transport sediments toward the leeward end of the reef. Diffraction

**Wave Shoaling and Refraction, Figure 6** Wave refraction on simplified form of Gannet Reef, southern Great Barrier Reef – effect of change of wave direction on cay location. Wave period 8 s; reef top water depth 2 m; only every fifth wave crest is shown on reef top (from Gourlay, 1988).

behind the reef will make the sheltered zone behind the reef less sheltered than might be expected. Interference of refracted waves on the reef platform may result in the formation of a windward shingle bank or cay, while sand cays form in the focal zone created by the refracted waves toward the leeward end of the reef. The shape and location of these interference and focal zones vary with changes in wave direction and wave period with consequent modification of the shoreline alignment of cays as their beaches respond to changes in alongshore transport around them.

## Definitions

*Sea*. Waves which are being acted upon by the wind that generated them. They are relatively short and steep with short crest lengths. Also called *storm waves*.

*Swell*. Waves which are propagating freely no longer under the influence of the wind that generated them. They are relatively long and flat with long crest lengths.

*Wave celerity C*. The velocity of the wave form. Also known as *phase velocity*.

*Wave height H*. The vertical distance between a wave crest and the following or preceeding wave trough (see Figure 6). Also described as *wave amplitude*  $a = H/2$ .

*Wave length L*. Distance between successive wave crests (see Figure 2).

*Wave period T*. Time interval between the passing of two successive wave crests at a fixed location.

*Wave frequency f* is the inverse of the wave period ( $f = 1/T$ ).

*Orbital velocity*. Velocity of the water particles during the passing of a wave.

*Significant wave height  $H_s$* . Mean height of the highest 33.3% of all waves in a wave record.

*Significant wave period  $T_s$* . Mean period of the highest 33.3% of the waves in a wave record.

*Root mean square wave height  $H_{rms}$* . Wave height which is equivalent to the height of a sinusoidal wave with the same energy as the recorded waves.

See also Chapters *Wave Shoaling and Refraction*; *Wave Set-Up*.

Mathematical symbols are defined where they first appear in the text or on a relevant figure.

The subscript o refers to the deep water values of the various quantities.

The descriptive terms used to describe coral reef morphology vary with the needs and previous practice of the various scientific disciplines. Those used in this entry and related ones (see Chapters *Wave Shoaling and Refraction* and *Wave Set-Up*) are defined in Gourlay and Colleter (2005, pp. 355–356) and in Figure 1 below.

## Introduction

Observations of ocean waves have been made by mariners and engineers for many centuries with empirical relationships being developed for practical use in the nineteenth century when the mathematical study of water waves also began. Scientific study of ocean waves essentially began during World War 2 when knowledge of sea conditions was required at specific locations where amphibious landings were to be made. Coastal engineers developed these new insights about ocean waves in the post World War 2 period using laboratory models and by applying the theoretical and practical knowledge that had been developed during the war. Measurements of ocean waves were first made for engineering purposes such as the design of breakwaters and other structures and for prediction of coastal sediment movements.

During the 1960s and 1970s, oceanographers and earth scientists increasingly built on these foundations with field experiments and new theoretical approaches, while, subsequently, engineers and mathematicians have developed mathematical models based upon these measurements and theories. The study of waves on coral reefs is comparatively recent, with the first significant scientific observations being reported in the mid 1970s (Roberts et al., 1975).

## Ocean waves and coral reefs

Ocean waves are one of the most important physical phenomena shaping the morphology and influencing the ecology of modern coral reefs. Waves passing over shallow reefs agitate the water over the reef surface and modify the flow within the coral matrix. When waves break on the edge

**Waves and Wave-Driven Currents, Figure 1** Definition figure for reef morphology terms.

or surface of a reef the water is aerated; pieces of coral are broken off and transported, together with larvae and other organisms; currents are generated on the reef-top; these wave-driven currents carry organisms and detrital material to other locations. Where planar reef platforms have developed, waves create windward shingle banks and islands, including *Atoll Islands (motu)* and also the sandbanks that develop into leeward *Vegetated Cays*.

There is a large spectrum of waves generated by various causes in the oceans surrounding coral reefs. The shorter period waves are generated by wind blowing over the water surface as various moving weather systems form, grow, and decay. These “wind waves” – sea and swell – have periods from a few seconds to about 20 or more seconds. The predictable tides generated by periodic changes in the gravitational attraction between the earth, moon, and sun are much longer, circa 12 or 24 h (see Chapter *Tidal Effects on Coral Reefs*). The moving weather systems also produce even longer waves such as the storm surge associated with *tropical cyclones (Tropical Cyclone/Hurricane)* and continental shelf waves associated with the passage of larger moving weather systems around large land masses such as the Australian continent. Apparently random events such as landslides and earthquakes may generate *Tsunamis*, long low waves that propagate rapidly over large distances of deep ocean before shortening and amplifying on shallow shelf margins or in confined bays with often disastrous results.

This entry is primarily concerned with wind-generated ocean waves and their transformation as they propagate around and onto reefs and into reef lagoons. As these waves transform and break on reefs they also cause wave-driven currents that are superimposed on the tidal and wind-driven current systems. Indeed in many situations the wave-driven

currents dominate the water circulation system on specific reefs. Important aspects of the reef-top wave system are treated in separate chapters – *Wave Set-Up*; *Wave Shoaling and Refraction*. Comprehensive treatments of the mechanics of water waves are available in Dean and Dalrymple (1991); Massel (1999) and Nielsen (2009).

### Wind-generated ocean waves

When wind blows across the surface of the ocean, that surface becomes unstable, developing small waves that propagate in the general direction toward which the wind is blowing. These waves increase in size as the wind speed increases and reach a maximum size, which depends either upon the duration of the wind event or the distance over which the wind is blowing. The propagation of wind waves over the ocean is governed by gravity, which acts to restore the disturbed water surface to its original smooth condition. Waves that are being acted on by the generating wind are known as sea or storm waves, whereas those that have escaped from the influence of the generating wind are known as swell (see definitions of *sea* and *swell*).

### Wave propagation

The basic mathematical theory used to represent ocean waves is the small amplitude or Airy wave theory, which represents waves as sinusoidal in form and assumes, among other things, that the wave steepness  $H/L$  is small (Figure 2). In its simplest form this is a linear theory which means that, if more than one wave train is present, the water movement of the resulting wave motion can be obtained by superimposing the water movements of the individual wave trains.

The size of ocean waves is measured in terms of their height  $H$  and their length  $L$  or period  $T$ , where  $L = CT$  (Figure 2).  $C$  is the celerity, which is the velocity at which an individual wave travels over the water surface. Wind-generated ocean waves are oscillatory waves which transmit wave energy across the ocean surface but do not transport water particles with them. Nevertheless, as waves travel across the ocean they cause the water particles to oscillate about a mean position as each wave passes. Oscillatory ocean waves are progressive, that is, they travel in a given direction. However, if they meet an obstacle – a reef, cliff, or breakwater – any of their energy not dissipated at the obstacle will be reflected as a wave traveling in the opposite direction. The superposition of the reflected wave on the original or incident wave will produce a partial or complete standing wave where the water surface oscillates up and down at distances located at half wave length intervals from the reflective obstacle. If the incident wave train approaches the reflective structure at an angle, it will be reflected with the same angle.

Gravity waves propagating in the ocean in most cases are initially deep water waves that propagate without influencing the bottom or being influenced by it. According to small amplitude theory their celerity  $C_0$  increases with their period, i.e.,  $C_0 = gT/2\pi$  and their wave length  $L_0 = gT^2/2\pi$ . This relationship applies when  $h/L_0 > 0.5$ , where  $h$  is the water depth.

As the relative water depth  $h/L$  reduces below 0.5, both the celerity and wave length are increasingly affected,

**Waves and Wave-Driven Currents, Figure 2** Definitions of wave height and wave length.

becoming smaller as  $h/L$  reduces, and when  $h/L \leq 0.05$  the waves are shallow water waves with  $C = \sqrt{gh}$ . That is, the wave celerity depends only upon the water depth. The celerity of intermediate depth waves depends upon both the wave period and the relative depth  $h/L$ , where  $L$  also becomes shorter as the depth becomes shallower (see also Chapter *Wave Shoaling and Refraction*).

The type of motion experienced by the water particles disturbed by waves also changes as the waves propagate from deep water into shallow water. In deep water the water particle orbits are circular in form with a diameter equal to the wave height at sea level and decreasing exponentially with increasing depth below that level (Figure 3). When  $h/L \geq 0.5$ , the orbital motion at the bottom is negligible. As waves propagate into increasingly shallow water, the water particle orbits become elliptical in shape with the horizontal motion becoming relatively larger than the vertical motion. In shallow water the horizontal motion is essentially the same at all depths, and there is significant oscillatory water motion at the bottom. In reality individual fluid particles also drift forward in the direction of wave propagation because the positive velocities along the upper parts of their orbits are greater than the negative ones along the lower parts. This process is known as mass transport and the total flow rate per unit length of wave crest generated by it is  $gH^2/8C$  (Nielsen, 2009).

The various formulae for calculating the properties of waves propagating from deep water into intermediate depths involve hyperbolic functions of the relative depth  $h/L$ , where  $L$  is one of the unknown properties. Hence, evaluation of these properties involves iterative calculations or the use of tables of previously calculated values. However, explicit approximations, where the wave properties  $C$ ,  $L$ , etc. are functions of  $h/L_0$ , are now available to simplify these calculations (Nielsen, 2009).

Ocean waves often appear to travel in groups of larger waves followed by groups of smaller waves – fishermen have long held the belief that every seventh or tenth or whatever wave is bigger than the others. Wave theory supports this general idea in that when two wave trains of slightly different wave length travel in the same direction, superposition of their wave forms results in the physical phenomenon known as beats. This involves a periodic variation of the amplitude of the basic wave frequency,

**Waves and Wave-Driven Currents, Figure 3** Wave orbital motion: (a) Shallow water, (b) intermediate depths, (c) deep water.

causing a series of wave groups that move in the same direction as the component waves but at a smaller velocity, the group velocity  $C_g$ .

Wind-generated ocean waves are short waves in that the effect of bottom friction upon their propagation and energy transmission is confined to a thin oscillatory boundary layer immediately above the bottom surface. By contrast, tide-generated waves, storm surges, and tsunamis are long waves in that they are shallow water waves in the ocean, and the effects of bottom friction create a boundary layer extending over the full water depth. Coral reefs generally have much rougher surfaces than most other coastal or shelf bottoms, and it is possible that in some situations wind-generated waves propagating over reefs may have long wave characteristics.

As an ocean wave train propagates across an initially still water surface it deforms that surface and potential energy is stored in the wave form. At the same time, the water particles acquire kinetic energy as they move in their wave-induced orbits. For small amplitude waves the potential and kinetic energies are equal to one another and the total energy per unit water surface area (energy density)  $E = \rho g H^2 / 8$ . Moreover, energy is transmitted in the direction of wave propagation at the group velocity  $C_g$ , which is less than the celerity. Hence, the wave power or energy flux of the wave train,  $P = EC_g$ . In deep water  $C_g = C_o/2$  and so,

$$P_o = \frac{\rho g^2 H_o^2 T}{32\pi}.$$

In shallow water  $C_g \rightarrow C$ .

The linear wave theory, on which the preceding description of ocean waves is based, assumes that surface gravity waves are regular sinusoidal waves of relatively small amplitude, that is, either  $H/L$  or  $H/h$  is small. In reality, ocean waves are neither regular nor have small amplitude. Furthermore, some important wave phenomena, such as wave breaking, wave set-up, and the wave-driven currents the latter generates, can only be explained when nonlinear terms associated with the water motion are considered (see Chapter *Wave Set-Up*).

Finite amplitude wave theories give alternative representations of ocean waves when either of the conditions  $H/L \rightarrow 0$  or  $H/h \rightarrow 0$  do not hold, for example, as waves approach the breaking condition. If  $H/L \rightarrow 1$ , Stokes theory with various orders of approximation represents deep water waves. First order Stokes theory is identical with small amplitude wave theory. The second order approximation, that is, including terms in  $H^2$ , has an asymmetric wave profile with the crest amplitude larger than the trough amplitude; crests are sharper and troughs are flatter than sinusoidal small amplitude waves (Figure 4a). It also predicts the mass transport of water particles in the direction of wave propagation. Third order Stokes theory predicts that the wave celerity, which according to small amplitude theory is proportional to the wave period, is also a function of wave steepness.

In shallow water, when the relative depth  $h/L \rightarrow 0$ , a second order solution of the linear shallow water long wave equations results in the cnoidal wave theory. Again these finite amplitude waves have sharp higher crests and flat shallower troughs than sinusoidal small amplitude waves (Figure 4b). Their celerity depends not only on the water depth, but also on the relative wave height  $H/h$ .

Stokes theory becomes increasingly unsatisfactory as waves enter intermediate depths, that is,  $h/L < 0.5$ , while cnoidal theory also is increasingly unsatisfactory as  $h/L$  increases above 0.05. See Nielsen (2009) for further discussion of the applicability of these theories.

### Wave breaking

Wave breaking occurs when oscillatory waves become unstable and are transformed into translatory waves that transport water in the direction of wave propagation. This will occur when the horizontal orbital velocity of the water particles at the wave crest exceeds the wave celerity or when their maximum vertical acceleration exceeds the gravitational acceleration. In deep water, ocean waves will break when their wave steepness  $H_o/L_o$  approaches 0.142 (or  $1/7$ ). This process is a gradual one and appears in the formation of increasing numbers of “white caps” on the sea surface as the wave crests spill and develop small rollers on their downwind side. Spilling breakers of similar form

**Waves and Wave-Driven Currents, Figure 4** Wave profiles for finite amplitude waves: (a) Stokes waves in deep water, (b) Cnoidal waves in shallow water.

occur when steep waves break on mildly sloping beaches. Less steep waves breaking on steeper beaches peak up, their forward face becomes vertical, and their crest plunges forward like a jet into the preceding wave trough. On even steeper beaches the lower part of the forward face of the wave becomes vertical and collapses like a partial plunging wave. Surging breakers occur when waves of low steepness break on steep beaches. The forward face of the wave remains relatively smooth and the wave runs up the beach with little foam or turbulence. The uprush–backwash cycle of a surging breaker is completed before the next wave surges up the beach (Figure 5).

The region where waves break is known as the surf zone. It may be divided into three subzones. There is an outer zone where the breaking waves rapidly change shape and develop a surf roller form. Potential energy is transferred into kinetic energy with little loss of energy. In the inner zone the surf roller becomes a bore or moving surge traveling landward over the seaward flowing undertow. Energy dissipation and *Wave Set-Up* occur in this zone. The swash zone occurs on the beach face where uprush and backwash of the breaking waves define the run up and run down limits (see Chapter *Wave Set-Up*, Figure 1).

**Waves and Wave-Driven Currents, Figure 5** Beach and breaker types for plane beaches.  $l_b = H_b^{1/2} / g^{1/2} T \tan \alpha$ , where  $H_b$  is breaking wave height and  $\tan \alpha$  is beach slope (reprinted from Gourlay, 1992, with permission from Elsevier).

## Irregular waves

Mariners and others accustomed to observing and experiencing ocean waves have been aware that the periodic regular waves conceived by mathematicians are an inadequate model for wind waves. Visual observations show that the height and period of successive individual waves vary considerably. Moreover, visual observations of wave height have been recognized as giving an estimated wave height somewhere between the actual mean wave height  $H_{av}$  and the largest waves  $H_m$  occurring at the time of observation. The advent of wave recorders produced many short records of a hundred or more waves of different heights and periods. The concepts of significant wave height  $H_s$ , root mean square wave height  $H_{rms}$ , significant period  $T_s$ , and zero crossing period  $T_z$  (Figure 6 and definitions) have been developed to characterize the waves in a given wave record. Statistical theory provides a theoretical wave height distribution – the Rayleigh distribution – which relates  $H_s$ ,  $H_{rms}$ , and  $H_{av}$  to the percent of waves in the record equaling or exceeding a given height.  $H_{rms} (=H_s/\sqrt{2})$  is the wave height equivalent to a sinusoidal wave with the same energy as the recorded waves. The maximum wave height in a given record follows an extreme value distribution, increasing as the number of waves recorded increases.

Using  $H_s$  to characterize the short term statistics of each wave record of say 20-min duration, the long-term statistical occurrence of wave heights can be obtained by using an exceedance plot for  $H_s$  at a given location, in which a given value of  $H_s$  is plotted against the percent of time it is equalled or exceeded. However, a more fundamental and physically meaningful long-term wave statistic would be one based upon the maximum value of  $H_s$  during various independent storm events.

The sea surface is continually changing. Since the wave celerity in deep water depends upon the wave length or wave period, the various waves present are continually moving in and out of phase with each other. The resulting sea surface is quite irregular and often consists of alternating groups of high and low waves. Moreover, the highest waves do not persist but are randomly distributed in space

**Waves and Wave-Driven Currents, Figure 6** Definitions of wave height and period ( $T_z$ ) in a record of irregular ocean waves.

and time. Such a sea surface can be approximated by the superposition of a large number of small amplitude wave trains from different directions. This leads to the concept of the wave spectrum in which the energy associated with a given frequency band has been determined for the full range of frequencies present in a given wave record (Figure 7). If the area under the wave spectrum diagram is designated as  $m_0$ , it can be shown that  $H_s = 4\sqrt{m_0}$ , so measurement of the wave spectrum gives an alternative estimate of the significant wave height  $H_s$ . The period  $T_p$ , corresponding to the peak of the frequency spectrum, is commonly used as the characteristic period for a given wave condition.

For wind-generated storm waves, the spectrum is broad, and  $T_p$  corresponds with a celerity approaching

the wind speed generating the waves. Swell waves have narrower spectra and larger values of  $T_p$  than storm waves. In open ocean and other situations, where locally generated wind waves are superimposed upon underlying swell, the wave spectra will have at least two peaks and hence two values of  $T_p$  (Figure 7).

A useful means of showing the variation of ocean wave conditions at a given location for a period of time is an  $H_s$ – $T_p$  scatter diagram (Figure 8). Such a diagram commonly will show an upper limiting curve where  $H_s \propto T_p^2$ , representing the maximum wind waves (sea) that can be generated at that site. In open waters this diagram also has a long tail with relatively low  $H_s$  but increasing  $T_p$  representing swell that has come from distant storms.

**Waves and Wave-Driven Currents, Figure 7** Ocean wave spectra (minor irregularities of spectral profiles have been removed) (A) Storm waves  $H_{os} = 4$  m,  $T_p = 9.5$  s; (B) wind waves  $H_{os} = 2.1$  m,  $T_p = 7$  s; (C) swell  $H_{os} = 1.7$  m,  $T_p = 14$  s; (D) sea and swell  $H_{os} = 1.5$  m,  $T_{p1} = 10$  s,  $T_{p2} = 4.4$  s.

**Waves and Wave-Driven Currents, Figure 8**  $H_{os}$  vs.  $T_p$  scatter diagram for ocean waves on southern side of Heron Reef, southern GBR: November 1996 to March 1997 (from Gourlay and Hacker, 2008a, p. 111).

### Wave transformation on reefs

"The interaction of physical processes with coral reefs is complex; each reef system has its own unique set of environmental and morphologic conditions" (Roberts et al., 1975, p. 234). The characteristics of ocean waves depend upon the climatic conditions generating them, and their transformation as they propagate over reefs is significantly influenced by the morphology of the reef system and adjacent or adjoining land masses. Moreover, wave transformation and accompanying wave driven-currents occur in water depths that vary with the periodic water level variations caused by the tides. Hence, the wave driven-currents are superimposed upon and interact with those generated by the tides, as well as with wind-driven currents. Climate, reef morphology, and tides all vary in different parts of the world and so do wave interactions with local coral reefs.

Reef morphology may vary from relatively wide fringing reefs with a flat seaward face fronting a beach to a narrow strip of steep-faced reef backed by a lagoon with a beach or reef behind it. Offshore reefs may be two-dimensional barrier reefs or three-dimensional island reefs usually with steep faces. Atolls have relatively narrow reefs with steep faces, enclosing a lagoon of sheltered water. Narrow reef islands (motus) prevent waves reaching the atoll lagoon except through the gaps in between the islands or passages through the reef. Some reefs are submerged at all times, and in many cases the coral growth on their surface provides a rough porous matrix which interacts strongly with the waves. In other cases reefs have reached the sea surface and have developed relatively smooth planar reef tops with different zones: smooth coralline algae, coral with many depressions but few projections, and even sandy reef flats. Where there is significant tidal variation of water levels the planar reef surface is generally at about the same elevation as the mean low tide level.

Several types of waves break on or travel around or across reefs. First, there are wind waves and swell from the surrounding ocean. Then there are short period waves, locally generated in shallow lagoons on the reef top or in larger deeper lagoons of atolls. Waves breaking on the reef rim release both shorter (secondary) waves and longer (infragravity) waves that alter the properties of waves traveling across the reef top.

Wave transformation over a reef varies depending upon which part of the reef is under consideration. Five zones can be distinguished. These are as follows:

- (1) The outer reef face where waves are affected by shoaling water but may not break
- (2) The reef edge where the larger waves generally break
- (3) The reef rim, between the reef edge and the reef crest, where smaller waves break and the breaking surge dissipates most of its energy
- (4) The reef flat or lagoon where the waves reform
- (5) The beach of either a reef island, continental island, or mainland, where the reformed waves finally break

On the outer reef face waves are subject to the processes of *Wave Shoaling and Refraction*. However, reef face slopes are very variable and so are their effects on waves. In some cases such as the ribbon reefs on the outer northern Great Barrier Reef (GBR) the reef face is almost vertical (Young, 1989). In these situations the effects of refraction and shoaling before breaking will be small, but significant reflection of wave energy may occur. Energy dissipation prior to breaking will be negligible but the actual breaking action on the reef edge will be very intense. Both field and laboratory observations indicate that on reefs with very steep faces the type of breaker is different from those observed on normal sloping beaches, being neither a plunging breaker nor a spilling breaker. The waves do not peak up significantly before breaking nor do they plunge but rather collapse into the strong backwash flowing seaward from the reef top.

On the flatter seaward faces of the Caribbean fringing reefs the bottom is much more irregular than on a sandy coast, and so significant energy dissipation may occur before the waves break (Roberts et al., 1975). Even where the reef face is steep but the water depth over the reef crest is relatively small, breaking waves may shape the seaward side of the reef crest into a ramp with a slope of the order of 1 in 8 to 1 in 15 where the waves break and dissipate a significant amount of energy before the breaking surge reaches the reef crest. In other situations the seaward part of the reef rim may develop a particular morphology created by the interaction between the waves and the growing reef structure. This is the characteristic spur and groove system (*Spurs and Grooves*) often found on the windward edges of reefs.

Normally waves break on the reef rim unless the water depth over it is large. For any given water depth over the reef the wave height on the reef increases with increasing ocean wave height up to a maximum limiting value. Thereafter, any further increase in ocean wave height does not increase wave heights on the reef. Indeed they may even reduce somewhat (Kono and Tsukayama, 1980). In some situations waves will pass over the reef rim at higher tide levels and travel across the reef flat or through the reef lagoon without breaking until they reach a cay or mainland beach where they finally break. Submerged reefs may only experience breaking wave conditions with large waves, and all wave action may pass over the deeper reefs without any breaking.

The width of the surf zone on the rim of a near horizontal reef is of the order of a few wave lengths. Laboratory data (Nelson and Lesleighter, 1985; Gourlay, 1994) show that the initial breaking process on a reef with a steep face is completed within one wave length from the reef edge. The distance from the reef edge to the end of the surf zone where the waves reform varies from three wave lengths upward depending upon the ratio between the ocean wave height and the water depth over the reef. For typical conditions within the GBR region, for example, waves of 3 m height and 6 s period breaking on a reef with 2 m of water over it, this zone would be 100–125 m wide. In exposed conditions on the outer barrier with a 3 m swell of 10 s

period in the same water depth the surf zone would be 160–200 m wide. Extreme waves of 8 m height and 10 s period in the same depth would create a surf zone 300–400 m wide.

The height of the reformed waves at the leeward side of the surf zone is limited by the water depth. Field studies at John Brewer Reef in the central GBR indicate that after the completion of wave breaking the maximum significant wave height is 0.35–0.4 times the water depth over the reef flat and that the maximum wave height in most cases does not exceed 0.6 times the water depth (Hardy and Young, 1996). Laboratory data (Nelson, 1987; Gourlay, 1994) confirm that the maximum  $H/h$  value for waves propagating over horizontal bottoms or very flat slopes is about 0.55. However, higher order approximations of nonlinear wave theories indicate that, when waves propagate in water of constant depth, the maximum possible value of  $H/h$  is close to 0.78. This value is commonly used in coastal engineering practice to determine where waves break on beaches outside coral reef regions. When the presence of higher harmonics generated on a horizontal bottom or at an abrupt depth change is considered, wave theory predicts a maximum  $H/h < 0.6$  (Massel, 1996).

Field observations on various reefs in different parts of the world show that waves are very much changed as they travel across a reef flat. Not only do wave heights become smaller because of breaking and frictional resistance but the wave spectrum broadens as energy is transferred to both higher frequencies (shorter periods) and lower frequencies (infragravity waves). Breaking waves are highly nonlinear, and secondary waves, which are harmonics of the primary wave period, develop during the shoaling and breaking process. Consequently, the reformed waves generally have shorter periods than the incident ocean waves as the primary wave and one or more secondary waves travel across the reef (Figure 9). This may be particularly the case for long swells (Wiegel, 1990). The lower frequency infragravity waves are responsible for the surf beat that causes fluctuations in the mean water level (dynamic set-up) in the surf zone (see Chapter *Wave Set-Up*). Where water is ponded on the reef flat at low tide, local winds may generate short period waves ( $1 < T < 3$  s) on the ponded water.

Significant energy losses occur as waves propagate across coral reefs. Observations in both the field and laboratory models indicate that the energy dissipation of waves breaking on coral reefs varies between 72 and 97% of the incoming wave energy (Roberts et al., 1992; Gourlay, 1994; Brander et al., 2004). This energy dissipation is caused by both bottom friction and wave breaking (Gerritsen, 1981). As reef surfaces are much rougher than those of sandy beaches by a factor of at least 10–20 times (Nelson, 1996), a relatively greater proportion of energy dissipation over coral reefs is caused by bottom friction. With relatively small waves passing over a shallow reef, friction dissipates a larger proportion of the wave energy than wave breaking (Lowe et al., 2005). Bottom friction also will have a relatively greater effect than wave breaking

**Waves and Wave-Driven Currents, Figure 9** Multiple crested secondary waves on reef flat, Rarotonga, Cook Islands, South Pacific Ocean. Photo: Michael Gourlay, March 1995.

on flatter reef face slopes and wider reef flats. As the size of the waves increases the proportion of wave energy dissipated by breaking increases, and eventually dissipation by wave breaking will dominate when waves are large.

While the beaches of reef-protected shorelines vary in form from place to place, these beaches are often relatively steep ( $\tan \alpha > 0.1$ ) with a plane face and are formed of medium to coarse coral sand. At low tide, no waves reach the beach since the waves break on the reef rim. However, as the tide rises, some reformed waves travel across the reef flat or shallow lagoon and break directly on the beach face. If these waves are steep ones they will plunge onto the beach and their energy will be dissipated in the uprush–backwash cycle on the upper beach face. If, on the other hand, waves of low steepness, such as long swells, pass over the reef rim and the reef flat without decomposing into secondary waves, the breakers will surge up the beach with little energy being dissipated. The latter waves have considerable potential to overtop the beach crest and move sand landward, so increasing the height of the beach crest. Moreover, on narrow reef flats the longer period infragravity waves can produce resonant oscillations of water level, which dominate the wave uprush process on a reef-protected beach (see Chapter *Wave Set-Up*).

In a study based upon three coral reefs with different morphologies and hydrodynamic (wave and tidal) conditions, Kench and Brander (2006) found that the effect of incident wave energy in reshaping reef-protected beaches depends upon a reef energy window index  $\psi = (\text{mean reef flat water}$

depth at high spring tide)/(reef width). A narrow reef width with a low reef flat elevation has a large value of  $\psi$ , indicating that more wave energy will cross the reef and break on the island shoreline, whereas a wide reef with a high reef flat elevation has a low value of  $\psi$ , indicating that most wave energy will be dissipated on the reef rim and relatively little of it will reach the island. Rising sea levels and disintegration of reef top corals following coral bleaching events have the potential to increase the depth of water over a reef flat, thus increasing  $\psi$  and making reef islands more vulnerable to erosion (Sheppard et al., 2005).

In the tropical latitudes where coral reefs flourish, winds and waves vary seasonally. For example, South Maalhosmadulu Atoll in the Maldives lies at latitude 5°N. It is subject to both westerly and northeasterly monsoon conditions with the former lasting longer (8 months) and also producing greater incident wave energy on the atoll and its reefs than the latter. Underlying swell from the south also refracts around the atoll delivering greater energy to its western side, independently of monsoon conditions. On an atoll scale these seasonally changing wave energy conditions control the formation, shape, and location of reef islands on the various small reefs forming the atoll, whereas on a reef scale they cause seasonal fluctuations in the positions of island beaches (Kench et al., 2006). Waves on the windward sides of reefs and cays are generally larger and shorter than those on the leeward sides, resulting in higher windward reef flat and beach ridge elevations (Kench et al., 2009; Samosorn and Woodroffe, 2008).

At Raine Reef, one of the outer reefs of the northern GBR (latitude 11° 36' S), southeasterly trade winds dominate during the winter months and northwesterly monsoon winds occur during most summers. Swells from distant tropical cyclones in the Coral Sea also reach this reef during summer, and occasional, generally small, tropical cyclones may affect it directly. Wave transformation across this relatively small reef platform is very much a three-dimensional process (see Figure 7 in Chapter *Wave Shoaling and Refraction*) and has resulted in the formation of a large cay located at the leeward end of the reef under the influence of the dominant southeasterly waves. Northwesterly monsoon waves transport sediment eastward along the northern beach, often creating a recurved sand spit at the eastern end of the island. During the subsequent winter southeasterly waves transport much of the sand from this spit along the southern shore of the island to its southwestern corner. Hence, seasonal variations in winds generate waves that cause a clockwise movement of sand around this reef island.

Many of the field experiments involving waves breaking and propagating across coral reefs have been undertaken at relatively sheltered locations or at times of low energy conditions. The duration of measurements in most cases is no more than a week or two. Conclusions based upon the experimental data obtained from such experiments may not be valid when more energetic conditions, that is, cyclonic/hurricane wave conditions, occur. In many cases significant sediment movement and morphological changes on reefs or reef-protected shorelines only occur during

extreme events and even then only when reef top water levels are elevated above normal levels by wave set-up, high tides, storm surge, or tsunami.

### Wave-driven currents

Surfers and fishermen have been aware for a long time of the existence of wave-driven currents, such as alongshore currents, rip currents, and undertow, within the surf zone of beaches. Earth scientists and engineers concerned with coastal structures also have been aware of the transport of sand and gravel along coasts by waves and the problems this transport can cause when breakwaters are constructed to form new harbors or to stabilize river entrances. However, it was not until mathematical physicists such as Longuet-Higgins and Stewart (1964) extended the sinusoidal (small amplitude) wave theory to include the concept of wave thrust or, as they described it by analogy with electromagnetic waves, radiation stress, that a proper scientific understanding of the mechanism driving the various surf zone currents was developed. This theoretical analysis also predicted that the waves would produce changes in the mean water level as they approached a beach: wave set-down offshore of the surf zone and wave set-up within the surf zone (see Chapter *Wave Set-Up*).

Initially wave-driven current systems were observed on fringing reefs on various islands in the Caribbean and Pacific regions. In some locations the reefs were relatively narrow and were backed by lagoons so that the reefs functioned as submerged breakwaters. At Grand Cayman Island in the Caribbean the waves discharged water over the reef rim into the lagoon where it flowed parallel to the reef crest and shoreline and discharged seaward through a channel at the end of the reef (Roberts et al., 1975; Roberts, 1981). Similar wave-driven current systems were observed at Guam in the northern Pacific Ocean where the water returned to the ocean through channels in the reef rim, associated with rivers (Marsh et al., 1981). Tidal ranges were generally less than 1 m.

The extensive Ningaloo Reef is located in the Indian Ocean on the edge of the continental shelf close to the Western Australian coast. Waves breaking on this westward-facing reef were observed to generate a landward flow across the reef with return circulation in the lagoon between the reef and the mainland. Water returned seaward through channels through the reef north and south of the inflow zone. The spring tide range was almost 2 m (Hearn et al., 1986).

In most of these cases, waves breaking on the reef rim transport water landward across the reef flat into shallow lagoons between the reef and the mainland. The flow then runs parallel to the shoreline until it reaches a gap in the reef or the end of the reef, where it flows seaward back to the ocean. Where the outflowing current is sufficiently strong, sediments on the reef flat or lagoon bottom are likely to be transported offshore and deposited in deep water sinks from which they cannot be returned to the reef system (Roberts, 1981). Navigation channels dredged

through the rim of coral reefs always carry this risk, unless specific action is taken to prevent it occurring. The boat access channel at Heron Island in the southern GBR is an example of this type of situation (Gourlay and Hacker, 2008b) (see Chapter *Infrastructure and Reef Islands*).

On offshore barrier or platform reefs, waves breaking on the windward reef rim transport water across the reef flat either over the leeward reef rim or in the case of atolls into the lagoon behind the reef. Such currents have been observed at John Brewer Reef and other locations in the GBR system (Young, 1989; Hardy et al., 1991). The velocities of these wave-driven currents have been found to be approximately proportional to the height of the waves causing them (Hearn and Parker, 1988; Symonds et al., 1995).

When waves approach the reef rim at an angle, they will be refracted as they travel across the sloping reef face and break either there or on the reef rim. Breaking waves that cross the reef rim at an angle will generate an alongshore current similar to that generated when waves break at an angle to a beach (see Chapter *Wave Shoaling and Refraction*). The actual directions of flow of wave-driven currents on reef tops depend upon several factors, including the direction of the ocean waves relative to the reef platform, the water depths over the reef top, the reef morphology, the roughness of various zones on the reef, etc. In general, currents flow from the breaker zones where wave set-up is highest to the lower portions of the reef top or to gaps in the reef surrounding a lagoon.

Laboratory models of small platform reefs in the GBR demonstrated these principles quite clearly (Gourlay, 1993; 1995). A model of Raine Reef on the northern outer barrier showed how wave set-up at the windward eastern end of the reef drives a current down the center of the reef and around the coral cay at its leeward end. A model of North Reef in the southern Capricorn region showed how the presence of a windward shingle bank obstructs the longitudinal flow, particularly at low tide levels, forcing it to follow a path defined by the lower levels on the reef top.

### Modeling wave-driven flow across reefs

Researchers modeling wave-driven flow across reefs have assumed a two-dimensional reef profile with a seaward sloping reef face and a horizontal reef top. Waves break on the sloping reef face, dissipating their energy and generating wave set-up. The maximum set-up  $\bar{\eta}_r$  occurs at or near the reef edge, that is, at the seaward side of the horizontal reef top. This maximum set-up creates the pressure gradient required to drive the wave-driven flow across the reef top since the water level at the downstream side of the reef is assumed to be the same as that seaward of the surf zone. The various approaches for modeling wave-driven flow across reefs have been reviewed by Gourlay and Colleter (2005) and Monismith (2007).

The mathematical models are based on the depth-integrated (one-dimensional) equations of motion for steady free surface flow, that is, the momentum equation incorporating the wave thrust, and the continuity equation.

The various researchers make different assumptions in applying these equations to wave-driven flow across a reef. Symonds et al. (1995) assume that  $\bar{\eta} \ll h$  at all places, that is, the set-up is not included in the water depth so  $\bar{\eta} + h$  is replaced by  $h$ . They also assume that the breaking wave height is linearly related to the depth at the break point and that this ratio  $\gamma$  is the same throughout the surf zone and on the reef top. Their friction term is a linear function of the wave orbital velocity, and there is no shoaling or friction offshore of the break point. In contrast, Hearn (1999) does not assume that set-up is small in comparison to the water depth. Furthermore, he assumes that the breaker index  $\gamma$  has different values at break point, in the surf zone, and on the reef top. He also ignores friction both offshore and in the surf zone, but considers the very significant effect of large reef top roughness in creating frictional resistance to the wave-driven flow. Massel and Brinkman (2001) extend the model of Symonds et al., using a more detailed representation of the breaking process, while Lugo-Fernandez et al. (2004) allow for a continuous decrease in wave height across the submerged reef crest.

The model of Symonds et al. produces a simple analytical solution with the friction coefficient only occurring in the scaling parameter for velocity, so the magnitudes of both the wave set-up and the sea surface slope across the reef top are independent of friction. Their solution predicts a reduction in set-up when there is a flow across the reef but it can not give meaningful results when ocean tide levels approach reef top elevation, that is, when  $\bar{\eta} \geq h$ , nor for steep-faced reefs when waves break directly on the reef edge. Hearn's model predicts that the wave set-up is identical to that predicted by Tait (see Chapter *Wave Set-Up*) and that its magnitude is unaffected by the flow. The models of both Symonds et al. and Hearn qualitatively agree with Gourlay's laboratory experiments in that the velocity  $V_r$  of the wave-driven flow over a reef increases from zero when the ocean water level rises above reef top level, increasing to a maximum with increasing water depth and then decreasing as wave breaking and hence wave set-up reduce, finally becoming zero again when the depth on the reef top equals/exceeds the depth at which waves pass over the reef without breaking. Hearn showed that some deeper reefs, for example, Kaneohe Bay, are in the regime of decreasing wave breaking, and hence the current velocity reduces with increasing water depth while many shallower reefs, e.g., Ningaloo, are in the regime in which the current increases with increasing depth.

Overall, these approaches are restricted to reef situations where the reef face slopes are relatively flat and waves generally break a significant distance seaward of the reef crest. Moreover, their results may not be meaningful for very shallow water depths over the reef top. Terms involving  $V_r^2$ , representing the friction and kinetic energy of the current, are not always considered.

Various researchers, for example, Kraines et al., 1998; Angwenyi and Rydberg, 2005, have applied these or

similar approaches to numerical models of specific sites, involving reefs and bays, where wave-driven currents are superimposed upon the dominant tidal current circulation.

### Wave pumping

Another approach to wave-driven currents on coral reefs is the wave pump analogy. An early presentation of the wave pump was given by Bruun and Viggoson (1977). Essentially, the waves breaking on the reef rim act as a pump lifting water from the ocean and discharging it onto the reef top or into the lagoon behind the reef. The water pumped onto the reef or into the lagoon then flows back to the sea over the leeward side of the reef in accordance with open channel flow theory. The directions of flow on the reef top will be controlled by the reef morphology with flows tending to concentrate at the lower portions of the reef rim or in channels through the reef enclosing the lagoon. The wave pump is most efficient on steeper faced reefs.

As explained in the Chapter *Wave Set-Up*, waves breaking on the reef face/rim raise the mean water level in the reef top surf zone above the ocean water level. If this water cannot escape, the mean water level surface, or wave set-up, over the reef top landward of the surf zone is horizontal, and the only return flow to the ocean is the backwash over the reef rim between breaking waves. Such a situation rarely occurs in nature but can be easily simulated in the laboratory. Where the water can escape over a portion of the reef rim behind the surf zone then it will flow toward that area. As it does so, some of the potential energy of the wave set-up will be converted into kinetic energy (proportional to  $V_r^2/2g$ ) and the reef top wave set-up will be reduced by this amount. Furthermore, the flow of water on the reef top will be resisted by friction on the relatively rough reef surface, and this will dissipate an increasing

amount of energy as the distance between the surf zone and the leeward side of the reef increases. This energy dissipation by friction will be accompanied by a fall in the mean water level in the direction of flow.

The basic processes of the wave pump generating wave set-up and associated open channel flow across a reef top have been explained through laboratory model experiments in a wave flume (Gourlay, 1996a, b; Gourlay and Colleter, 2005). This model reproduced a steep-faced reef (slope 1 in 1) where waves broke at the reef crest and the resulting current flowed across a horizontal reef top. Following the suggestion of Munk and Sargent (1954), it was found that the wave set-up on the reef was proportional to the wave power or energy flux. Consideration of the conservation of wave power (Figure 10) leads to the following statement

$$P_o = P_R + P_D + P_r + P_v,$$

where  $P_o$  is the ocean wave power approaching the reef,  $P_R$  is the wave power reflected from the reef face,  $P_D$  is the wave power dissipated by wave breaking,  $P_r$  is the wave power transmitted across the reef top, and  $P_v$  is the power of the reef top current.

The various forms of the wave power can be expressed in terms of the ocean wave conditions, the current velocity, and the water depth on the reef top. Subsequent substitution and algebraic manipulation lead to a mathematical expression for the characteristic curves of the wave pump in terms of the following dimensionless parameters:

$$N = f(S, q^*, H_o/L_o),$$

where  $N = \bar{\eta}_r/T\sqrt{gH_o}$  is the dimensionless maximum wave set-up;  $S = d_r/H_o$  is the relative submergence of the reef ( $d_r = \bar{\eta}_r + h_r$ );  $q^* = q/g^{1/2}H_o^{3/2}$  is the dimensionless

**Waves and Wave-Driven Currents, Figure 10** Definitions for wave pump theory for wave-driven flow across a coral reef (reprinted from Gourlay and Colleter, 2005, with permission from Elsevier).

flow per unit length of reef rim;  $H_o/L_o$  is the ocean wave steepness ( $L_o = gT^2/2\pi$ ).

This theory predicts that the wave set-up driving the flow across a platform reef is less than the set-up generated by the same wave conditions on a fringing reef where no flow is generated. When submergence  $S = 0$ ,  $\bar{\eta}_r = -h_r$ , that is the water level  $h_r$  is below the reef top elevation, and the waves are breaking on the reef face. In this case, the maximum value of  $N$  coincides with the dimensionless wave run-up (see *Wave Set-Up*) that just reaches the crest of the rough reef face. No flow across the reef occurs when  $N = 0$  and this occurs when  $S = 2.5$ , which is equivalent to  $H_o = 0.4h_r$ , the condition for waves to pass over the reef without breaking.

To determine the wave-driven flow on the reef top it is also necessary to know the reef top flow characteristics. The basic equation of motion can be simplified for steady flow in an open channel. Subsequent integration leads to the well-known Bernoulli equation as applied to open channel flow. Consideration of flow energy leads to a condition that indicates that for any given flow there is a particular critical depth at which the flow energy is a minimum. Moreover, there is a larger depth where the flow is relatively slow and deep (subcritical flow) and a smaller depth of fast shallow flow (supercritical flow). In subcritical flow small disturbances can travel both upstream and downstream but in supercritical flow they can only travel downstream.

Wave-driven flows across a coral reef are usually subcritical and are controlled by reef top roughness and downstream water level (reef top control). However, when flow rates are relatively large and/or the falling downstream ocean tide level approaches or falls below the reef

top level, critical conditions will occur on the reef rim and the reef top flow and water levels will be controlled by the downstream reef rim acting as a broad crested weir (reef rim control) (Figure 11).

A combination of the wave pump relationship with open channel flow theory for either reef rim or reef top control leads to analytical relationships for the reef top flow. These relationships allow the development of characteristic curves for a given reef. These characteristic curves show the variation of  $V^*$  ( $= \frac{V_r}{\sqrt{gH_o}}$ ) and  $q^*$  as functions of submergence  $S$ . The reef top characteristic curves are also functions of parameters involving the ocean wave conditions  $H_o$  and  $H_o/L_o$  and the reef top conditions  $K_p, f$ , and  $L_r$ .

Figure 12 shows the reef top characteristic curves for wave-driven flows on the laboratory model and at Heron Island in the southern GBR. There are two basic curves for a given reef, intersecting at a critical value of submergence  $S_c$ . The left hand curve ( $0 < S < S_c$ ) represents reef rim control, that is, the downstream reef rim acts as a broad crested weir; the right hand curve represents reef top control where the flow depends upon the water level difference between the surf zone and the downstream ocean water level, together with the friction factor for the reef top. For given wave conditions the velocity of the wave-driven current is a maximum when  $S$  equals  $S_c$ .  $S_c$  will vary within a relatively small range for a given reef depending upon the wave conditions. In contrast, the maximum flow occurs when  $1.5 < S < 2$ , that is, when the water depth over the reef is relatively large and the flow

**Waves and Wave-Driven Currents, Figure 11** Wave-driven flow across a horizontal reef: (a) Reef top control, (b) reef rim control (reprinted from Gourlay and Colleter, 2005, with permission from Elsevier).

**Waves and Wave-Driven Currents, Figure 12** Reef top characteristic curves for wave-driven flow: (a) Velocity parameter  $V^* = V_r / \sqrt{gH_o}$  versus Submergence  $S = d_r/h_o$ , (b) Flow parameter  $q^* = q / \sqrt{gH_o^3}$  versus Submergence  $S = d_r/h_o$ . Solid line model horizontal reef, broken line Heron Reef, southern GBR: (1) larger waves, (2) smaller waves, (3) cyclonic waves, (4) storm waves, (5) commonly occurring waves.

velocity is less than its maximum possible value. Both  $V_r$  and  $q = 0$  when  $S = 2.5$  when the waves pass over the reef without breaking. As would be expected the narrower, smoother, steep-faced model reef experiences relatively larger velocities and flows than the wider, rougher, flatter faced reef at Heron Island.

The theory for the wave-driven current in the reef top control regime, that is, the right hand part of the reef top characteristic curves, can be simplified to show that, for a given reef:

$$V_r = C_r \left( \frac{H_o T^{\frac{1}{2}}}{d_r^{\frac{1}{2}}} \right) ([1 - 0.16S^2])^{\frac{1}{2}},$$

where  $C_r$  depends upon the characteristics of the reef. This equation indicates that the flow velocity is approximately linearly related to the ocean wave height as found by both Hearn (1999) and Symonds et al. (1995), as well as Tartainville and Rancher (2000).

Wave pumping provides a very effective mechanism for flushing atoll lagoons, particularly those that are

completely enclosed by a reef with no channels through its rim. This process has been observed at Manihiki Lagoon in the northern Cook Islands, South Pacific Ocean (Callaghan et al., 2006). Careful measurements of water levels to an accurate common datum showed that the lagoon water level was at all times above the ocean water level, so the ocean tide was not driving the flushing of this lagoon system, even though the lagoon water levels fluctuated with a reduced amplitude in response to the periodic fluctuations in the ocean tide level. Lagoon water levels, averaged to exclude the tidal fluctuations, were found to closely follow the hindcast ocean wave energy flux over a period of several days. Observations on the windward side of the reef confirmed that the breaking waves pumped water on to the reef flat, lifting the water above ocean tide level. On the leeward side of the lagoon water flowed out over the reef rim under critical flow conditions. The wave-driven flow and flushing of the lagoon have been simulated by both analytical and numerical models.

Ocean waves and the reef top currents caused by them at the western end of Heron Reef in the southern Great Barrier Reef were measured over a 12-month period from mid March 1996 to mid March 1997 (Gourlay and Hacker, 2008a, b). Mild conditions, when wind speed was less than 5 m/s and  $H_{os} < 0.5$  m and tidal currents completely dominated on the reef top, occurred over only 45 tidal cycles (7%) during this period, even though the maximum tidal range was greater than 3 m. During the greater part of the year waves influenced the reef top currents at the two measuring sites close to the western end of Heron Island and on either side of the boat harbor and its access channel (Figure 13) (see also Figure 2 in Chapter *Infrastructure and Reef Islands*). Rising tides flowing over the western end of the reef, in through the boat harbor entrance channel and over the harbor bund walls onto the reef flat on either side of the island, were observed to be reversed by wave-driven currents – northeasterly winds/waves reversed currents on the northern side of the island and southeasterly winds/waves reversed currents on the southern side. In some cases, where winds blew along the axis of the island and ocean waves on either side of the reef had similar heights, westward currents occurred along both sides of the island. When waves are sufficiently large ( $H_{os} > 1.5$  m), continuous inflow to the harbor occurs throughout the tidal cycle (Figure 14). For large waves and small tides the westward wave-driven flow varies with the waves rather than the tide. For large tides and smaller waves, the westward flow velocity varies with the tidal cycle and the maximum velocity occurs when weir control develops over the bund walls at low tide. Under commonly occurring wave ( $H_{os} < 1.5$  m) and tidal conditions, the maximum wave-driven currents on the reef top were usually no larger than 0.3–0.4 m/s. However, during the three storm events recorded during this 12-month period ocean waves reached 3 m height and currents were of the order of at least 0.6 m/s (Figure 14).

The observations of wave-driven currents on Heron Reef confirmed the prediction of Gourlay and Colleter's

**Waves and Wave-Driven Currents, Figure 13** Wave-driven flow into Heron Island boat harbor, southern GBR (reprinted from Gourlay and Colleter, 2005, with permission from Elsevier).

theory that the wave-driven current velocity increased with increasing  $H_{os}$  and decreasing reef top water depth. No consistent relationship was found between current velocity and wave period. A direct comparison of measured and calculated current velocities at the northern current meter site for tide levels when the tidal current was zero gives a relationship of the form  $V = C(H_{os} - H_{oscr})$ , where  $H_{oscr} = 0.3-0.5$  m is the threshold condition for a wave-driven current and the constant  $C$  is independent of tidal range (Gourlay and Hacker, 2008b, pp. 222–249). The measured velocities are somewhat lower than the calculated ones, and this could be attributed to the reef top being rougher than it was assumed to be and/or to the ocean wave heights used in the calculation not being reduced to allow for refraction as they propagated from the deeper water surrounding the reef platform onto the shallow reef top.

Most recently Hench et al. (2008), working at Moorea, French Polynesia, have observed wave-driven currents on a coral reef with a shallow lagoon separating it from a continental island and a narrow deep passage connecting the lagoon to the ocean. Tidal ranges during these observations were small (0.3 m), so the water circulation was primarily the result of the set-up caused by waves breaking on the reef. Hench et al. were unable to predict their observed wave set-up using either the theory of Hearn (1999) or that of Gourlay and Colleter (2005), but an empirical relationship was established between wave set-up on this reef and the wave height, wave period, and

the water depth over the reef. Circulation and exchange of water between this coral reef system and the adjacent ocean was largely determined by episodes of larger waves generated by remote weather events rather than periodic tidal exchange mechanisms.

Field measurements of both wave set-up and the levels of the reef and beach topography where they are made must be accurately related to a common fixed land datum. If this is not done, the water depths cannot be determined to sufficient accuracy to reliably compare observed values of set-up and current velocities with those derived from various theories.

### Summary

Knowledge of ocean waves comes from observation and measurements in the field, laboratory experiments, mathematical theories, and numerical models. Engineering works, modern warfare, and environmental management have all stimulated and contributed to scientific research concerning ocean waves and their influence on coral reefs.

Waves are one of the most important physical phenomena shaping the morphology and influencing the ecology of modern coral reefs and reef top islands. There is a large spectrum of ocean waves, ranging from wind waves, swell, tides, storm surges to tsunamis. This entry is concerned with wind waves and swell.

Small amplitude wave theory is a first order linear theory for oscillatory waves of sinusoidal form. It provides

**Waves and Wave-Driven Currents, Figure 14** Wave-driven currents dominate over tidal currents at Heron Reef, southern GBR – 27 July, 1996 (adapted from Gourlay and Hacker, 2008b, p. 179).

relationships between the wave length, wave period, wave celerity, and wave height as waves propagate from deep water, where waves are unaffected by the bottom, through intermediate depths, where the depth has an increasing effect, into shallow water, where the depth dominates the propagation of the waves (see also Chapter *Wave Shoaling and Refraction*). As waves propagate across the water surface, water particles disturbed by them move in closed orbits with negligible forward transport but energy is transmitted by the waves with a velocity less than the wave celerity.

Finite amplitude wave theories give a better representation of the form of real waves, that is, the peaks are sharper and the troughs are flatter than those of sinusoidal waves. Stokes theory applies for deep water waves, and the second order theory predicts a small net movement of water particles or mass transport in the direction of wave propagation. Cnoidal wave theory represents shallow water finite amplitude waves.

Waves break when their crests become unstable. In deep water this appears as white caps at the front of the

wave crests. In shallow water there are a series of breaker forms, spilling, plunging, collapsing, and surging, depending upon the steepnesses of both the bottom and the waves. The region between the break point and the shore is known as the surf zone, the final section of which is the swash zone on the beach face.

Real ocean waves are not periodic but irregular. The characteristics of real waves measured by a wave recorder are represented by the significant wave height or root mean square wave height, which are related to one another by the Rayleigh distribution. An alternative or complementary representation of irregular waves is the wave spectrum that measures amount of energy at different frequencies in a given short-term wave record.

The interaction of physical processes on coral reefs is complex, and wave transformation occurs in water depths that are constantly changing with the tides in different locations with varied reef morphology. The types of waves propagating on reefs include sea and swell from the surrounding ocean, short locally generated wind waves, secondary waves, and infragravity waves. Waves are affected by the rough reef face before breaking on the reef rim, after which they reform and travel across the reef flat and ultimately may break on the beach of a cay or other land mass. For any given water depth over a reef there will be a limiting wave height that can cross the reef without breaking. Both field and laboratory experiments indicate that the significant wave height of reformed waves on a reef does not exceed 0.35–0.4 times the water depth on the reef, and the maximum individual wave height is no more than 0.55–0.6 times the water depth. Reef surfaces are 10–20 times rougher than sandy beaches, and 72–97% of wave energy is dissipated as waves propagate across reefs. High and wide reefs dissipate much more energy than low and narrow reefs. Winds and the waves they generate vary seasonally, and these variations have significant implications for the formation, shape, and location of reef islands on individual reefs.

*Wave Set-Up* causes variations in mean water level on reefs, and the resulting water level gradients drive reef top current systems. Wave-driven currents flow from the exposed reef edge, where waves are breaking, toward the sheltered side of the reef and/or to lower parts of the reef top or atoll reef. Outflowing currents through both natural and artificial channels have the potential to remove sediment from the reef.

Mathematical models of wave-driven currents are based upon the depth-integrated equations of motion for steady free surface flow, that is, momentum equation incorporating wave thrust, and continuity equation. These models predict that the wave-driven flow over a reef increases from zero, as the ocean water level rises above the reef top level, to a maximum with increasing water depth and then decreases as wave breaking and wave set-up reduce, becoming zero again when waves pass over the reef without breaking. Such models also can simulate wave-driven circulation in the presence of tidal circulation. However, they are restricted to reefs with relatively flat reef face slopes and generally

do not produce meaningful results when water depths over the reef are very shallow.

The wave pump analogy regards the waves breaking on the reef as a pump lifting water from the ocean and discharging it onto the reef top or into the lagoon behind the reef. The pumped water then flows back over the leeward side of the reef in accordance with open channel flow theory. The wave pump can be applied to and is most efficient on steeper faced reefs. It can also be applied where reef top water levels are very shallow or even emergent, that is, above ocean water level. Reef top characteristic curves for a given reef show the increase in wave-driven flow from zero at very small depths to a maximum at much larger depths and then decreasing to zero when waves pass over the reef without breaking. They also show the different flow conditions when reef top control and reef rim control occur and the critical submergence when one form of control changes to the other. Field measurements show that wave pumping provides a very effective mechanism for flushing atoll lagoons, particularly those that are completely enclosed by a reef with no channels through its rim.

In open ocean situations, even when tides are relatively large (range  $\leq 3$  m), wave-driven currents significantly influence the reef top circulation system on platform reefs. On a particular reef, under commonly occurring wave (1.5 m height) and tidal conditions, the incoming tidal flow was completely reversed by wave-driven flow even though the maximum wave-driven currents on the reef top were usually no larger than 0.3–0.4 m/s. However, during storm events with ocean waves  $\leq 3$  m height, currents were at least 0.6 m/s. When tidal currents were insignificant, the wave pump theory gave a good prediction of reef top current velocities.

## WEST INDIAN CORAL REEF CLASSIFICATION

Jörn Geister  
 Naturhistorisches Museum Bern, Bern, Switzerland

### Definition

Coral reef classification: Assignments of single coral reefs or of parts thereof to reef types distinguished by their zonal structure. The present reef classification is ecological and based on the occurrence and distribution of certain coral associations (“facies zones”) that develop as a result of differential exposure to waves.

### Introduction

As a side result of his longtime taxonomic studies in the northern Red Sea, Benjamin Klunzinger (1870) described for the first time in great detail the zonal distribution of reef biota parallel to the front of a fringing reef. Almost 85 years later, a well-developed zonal pattern was reported again by Wells (1954) from Bikini atoll in the western Indo-Pacific Ocean. Wells (1954, 396) defined the “ecological zone” of a coral reef as “an area where local ecological differences are reflected in the species association and signalized by one or more dominant species”. Thus, distribution of reef builders is essentially controlled by “ecological differences” (primary environmental factors) such as substratum (soft or hard), water depth (diminution of luminosity with increasing depth), wave exposure and intensity of seasonal abrasion. All of these fore-mentioned factors are entirely physical in nature (Geister, 1975, 1980a).

From Jamaican reefs, Goreau (1959) presented a first detailed description of coral zonation in the western Caribbean Reefs region. Studying southwestern Caribbean reefs, Geister (1975) analyzed zonal patterns of the reef complex surrounding San Andrés Island, the reef zones being interpreted as facies units. The nature and causes of this and other benthic zonations, found both in Caribbean Reefs and Indo-Pacific reefs, were reviewed by Done (1983).

### Composite structure of shallow Caribbean coral reef types

The monograph of Geister (1975) provided a first attempt of an ecological classification of shallow West Indian reefs

based on the eye-catching zonal pattern of the frame-building biota (facies zones) corresponding to graduated exposure to waves.

Waves in the West Indies are essentially generated by the trade winds blowing with rather constant force from easterly directions. When incoming waves approach over the fore-reef slope of coral reefs, a gradual increase of bottom water movements is observed as an effect of shallowing. Maximum water movement is observed in the reef crest area where waves normally break (“breaker zone”). Decreasing hydrodynamic energy on the bottom behind the topographic crest is due to energy loss by wave friction and by the effect of gradual deepening.

Graduated wave exposure on ridge-shaped coral reefs is mirrored by striking sub-parallel facies belts of the reef building biota (Figure 1). These are both ecological and facies zones defined by dense growths of predominant hermatypic corals, mixed coral associations or other reef biota adapted to different degrees of wave exposure.

The wave zones recognized in Caribbean reefs are listed below, following a sequence of decreasing wave exposure:

- (1) **Melobesieae wave zone** (“algal ridge”)
 

Red algae forming massive algal encrustations
- (2) ***Palythoa-Millepora* wave zone**

*Millepora* spp. framework associated with the colonial zoanthid *Palythoa* sp.
- (3) ***strigosa-palmata* wave zone**

*Diploria strigosa* heads with *Acropora palmata* thickets
- (4) ***cervicornis* wave zone**

*Acropora cervicornis* thickets, almost monospecific
- (5) ***porites* wave zone**

*Porites porites* thickets, almost monospecific
- (6) ***annularis* wave zone**

*Montastrea annularis* (and related species *M. franksi* and *M. faveolata*) massive heads in mixed faunal complex including some branching species.

Where well-developed, an overall symmetrical arrangement of subparallel “wave zones” will be recognized from the fore-reef (“front wave zones”) to the back-reef area (“rear wave zones”). This composite zonal structure is best developed in crest-shaped subtidal reefs facing the incoming waves (Figure 1). It permits to define six basic reef types. Each reef type is recognized by and named after the wave zone community on the reef crest (“breaker zone community”). This breaker zone community reflects the maximum wave exposure characteristic for each reef.

We distinguish the following six basic “reef types” (Figure 1) arranged according to decreasing wave exposure:

Melobesieae reef > *Palythoa-Millepora* reef > *strigosa-palmata* reef > *cervicornis* reef > *porites* reef > *annularis* reef

Sequences of wave zones in front and to the rear of the breaker zone (reef crest) reflect successively more sheltered conditions on the sea bottom. If well developed, their

**West Indian Coral Reef Classification, Figure 1** Idealized complete zonal sequences of the six basic reef types present in West Indian reef complexes. Increase in relative degree of wave exposure is indicated by simple to multiple arrows. The uppermost profile represents a reef exposed to maximum wave energy, the lowest to a minimum. The scheme shows a successive dropping out of high-energy associations with decreasing wave exposure and a shift of deeper water associations to shallower locations on sheltered reefs. Zonal sequences are normally incomplete, commonly with zonation gaps in the fore-reef and back-reef areas. Modified from Geister (1983).

zonal sequence may be rather complete as shown in Figure 1. But more frequently, parts of the front and rear wave zones are missing leaving empty zonal gaps.

Incomplete or irregular series of wave zones result from irregular bottom topography in front or rear of the crest, from steep break-offs, unusually shallow reef flats, substrate changes from reef to lagoon facies (unsuitable substratum of loose sediments for settling corals!) and from rocky surfaces exposed to extreme seasonal storm waves causing abrasion (see Geister, 1977: Figure 1). The distribution of these six basic reef types within the reef complex of San Andrés Island was presented in a map (Geister, 1975: Figure 23).

Comparable studies in the Indian Ocean (Rosen, 1975) suggest that the same principles of wave zonation are effective both in Caribbean Reefs and Indo-Pacific coral reefs. Exact comparison, however, is necessarily bound to reefs of the same faunal realm.

### Regional and local distribution of reef types

Reef classification based on ecological zonation facilitates comparative studies of regional reef distribution and reef mapping at scales ranging from single small patch reefs up

to large reef complexes. Thus, a follow-up study (Geister, 1977a) analyzed the geographic range of these reef types over the entire West Indian faunal province. Regional distribution of reef types mainly concerns seaward reefs around oceanic islands, atolls, and in front of continental coasts but also fringing and patch reefs within the lagoons of barrier reefs and atolls (Geister, 1975, 1977a, 1983, 1992; Geister and Diaz, 1997; Diaz et al., 2000; Geister and Diaz, 2007).

Reefs of **extreme wave exposure** (Melobesiaee reefs) are regionally restricted to areas facing a maximum windward fetch of the trade winds reaching up to 2,000 or more kilometers in length. Thus, these reefs are best developed along the eastern shores of the Lesser Antilles (Adey and Burke, 1976), where they receive the full impact of the Caribbean Reefs swell. Melobesiaee reefs at the western ends of the Caribbean Sea and Gulf of Mexico are restricted to particular local topographic conditions where wave refraction and interference enhance local wave intensity (San Andrés Island, Providencia, San Blas/Panama, etc.).

Reefs of **high wave exposure** are those of the *Palythoa-Millepora* type. They are best developed in the unprotected windward tracts of the central Caribbean (Pedro Bank etc.) and in the atolls and island barrier

reefs along the Nicaraguan Rise and western Gulf of Mexico where the fetch of the trade winds attains around 500–2,000 km in length.

Seaward reefs of the *strigosa-palmata* type reflect **medium wave exposure**. They are found protected from the full impact of oceanic swell by a wide shelf area or land mass as in Jamaica (Goreau, 1959), or lie in leeward positions facing a continental coast (Caribbean coast of Colombia: Diaz et al., 2000). They also flourish in the wave shade of higher wave exposure reef complexes as at Belize or in the lagoons of barrier reefs and atolls.

Reef types reflecting **moderate** (*Acropora cervicornis*), **low** (*Porites porites*) and **minimum wave exposure** (*Montastrea annularis*) are mainly bound to protected lagoonal environments of major reef complexes. In addition, they flourish in the quieter waters of the lagoon floor at several meters of water depth (see Geister, 1975: Figure 23; Geister, 1992; Wallace, and Schafersman, 1977; Diaz et al., 1997). Where protected from oceanic swells, they may also characterize well-sheltered leeward sectors of atoll reefs, as at Belize.

Local variation in distribution patterns of reef types can best be observed within the lagoons of single atoll or barrier reef complexes (Geister, 1975; Wallace, and Schafersman, 1977; Diaz et al., 1997). There, patch reefs will be found distributed corresponding to the local wave exposure pattern (see Geister, 1975: Figures 6 and 23).

### Lateral transitions along a single reef tract from one to another reef type

Along a same seaward reef tract, wave exposure will decrease from exposed windward towards more protected leeward positions. It will also decrease at locations where the reef crest is submerged for several meters, or where diffraction of swell occurs. Hence, single seaward reef tracts of barriers or atolls may reveal zonation patterns of more than one reef type as here defined.

### Vertical transitions in time from one to another reef type and sea-level history

The three-dimensional zonal structure of modern reefs records Holocene sea-level history (Geister, 1983: Figures 49–54). This is exemplified by a standard reef composed of the following three wave zones: *M. annularis*, *A. cervicornis* and *A. palmata* that developed under conditions of stable, slowly rising, rapidly rising and falling sea level. Intermediate situations are common:

#### Horizontal zonation pattern (Type A)

As soon as a fairly stable sea level position was achieved for some extended period after the Holocene transgression, reef growth resulted in an essentially horizontal pattern of internal zonation: lateral growth widened the established facies zones. Growing vertically into higher energy levels, they were succeeded by the wave zone corresponding to the next higher energy level. Thus, vertical transitions from an *annularis* Reef, to a *cervicornis*

Reef and finally to a *strigosa-palmata* Reef are possible (Geister, 1983: Figure 49, 50).

#### Vertical zonation pattern (Type B)

As soon as renewed sea level rise equaled the rate of reef growth, a pattern of vertical parallel facies zones developed from a Type A reef into an overall U-shaped zonal structure. The facies zone of highest wave exposure is found in the center, and successively lower wave exposure facies will grow towards the outer margins of the reef body (Geister, 1983: Figure 51). This geometry corresponds to the “keep-up reef” of Neumann and Macintyre (1985).

#### Lens-shaped zonation pattern (Type C)

When sea level rise eventually surpassed the growth rate of the Type A reef, the latter was gradually enveloped by facies zones of successively lower hydrodynamic energy, thus resembling an onion peel structure (Geister, 1983: Figure 53). Characteristic for this reef type is an upward sequence of facies zones, which reflects decreasing wave exposure and final reef drowning (Blanchon and Shaw, 1995). Breaker zones are covered by facies of successively lower wave exposure. This geometry corresponds to the “give-up reef” of Neumann and Macintyre (1985).

#### Cap-on-cap zonation pattern (Type D)

The internal facies geometry of a reef growing during a period of relative sea level lowering is characterized by a cap-on-cap arrangement of facies zones indicating downward increase of wave exposure with time. It may eventually lead to the emergence of the crest as a rocky reef islet. The best modern examples from the Caribbean Sea are the emerging reefs of the Rosario Islands chain and neighboring Baru Peninsula in Colombia (Geister, 1983: Figure 54; Pl. 26/4).

### Occurrence and distribution of reef types in the Pleistocene of the West Indies

Of the six reef types defined herein for the modern Caribbean Sea, five were found in Late Pleistocene (mostly Sangamonian) reefs of the West Indies. Thus, modern reef types may also serve as models for comparative palaeoecological studies and for mapping of Pleistocene reef tracts (Geister, 1975: Figure 27; Geister, 1980b).

However, during a preliminary survey comprising the emergent reefs of the whole West Indian faunal province, no reefs corresponding to the *Palythoa-Millepora* type were encountered (Geister, 1980b). The reason may be that the fire coral *Millepora* was rare at that time and locally absent from Sangamonian reefs.

On the other hand, the *annularis* to *porites* wave zones in Sangamonian backreefs were locally dominated by extensive thickets of *Pocillopora* sp., a branching reef coral genus completely absent from modern West Indian reefs (Geister, 1977b, 1984: Figures 13 and 14).

## WESTERN ATLANTIC/CARIBBEAN, CORAL REEFS

Bernhard Riegl

Nova Southeastern University, Dania, FL, USA

## Definition and introduction

Scleractinian corals occur all throughout the western Atlantic; however, reefs are only formed in a belt between 32.3°N (Bermuda) and ~17.5°S (Brazil). The continuous reef belt occurs between 26.5°N (Florida) and 9.8°N (Colombia) with an isolated southern extension in Brazil, separated from the Caribbean reef belt by the Orinoco and Amazonas rivers, and Bermuda as an outlier to the north. The western Atlantic forms its own biogeographic province and harbors a unique coral fauna that diversified primarily after the closure of the Isthmus of Panama, but the evolution of which may have already begun in the Eocene. All reef types known from other reef areas also occur in the western Atlantic, but some reef types are unique.

## The coral fauna

The Caribbean/western Atlantic region is home to a unique coral reef fauna and therefore makes up a distinct biogeographic province. Within this province subtle difference further subdivides it into a Bermudian (lacking *Acropora*), northern (E-Florida/Bahamas), north-western (Gulf of Mexico, W-Florida), central (Mesoamerica, Antilles), and Brazilian subregion (Veron, 1995). The most distinct region is the Brazilian with several endemic species and an endemic genus (*Mussismilia braziliensis*, *M. hispida*, *M. hartii*, *Favia gravida*, *F. leptophylla*, *Siderastrea stellata*, *Millepora braziliensis*, *M. nitida*, *M. laboreli*; Leao et al., 2003; Amaral et al., 2008). The Brazilian fauna has

affinities to the Tethyan and Paratethyan Miocene faunas, where these genera were common (Leao and Kikuchi, 2005).

Within the Atlantic Ocean, only the western region supports coral reefs. The easternmost Atlantic harbors corals, but no true reef building, although some dense coral growth is reported from the Gulf of Guinea and the Cape Verde Islands (Laborel, 1974; Moses et al., 2003). The Mediterranean, up to the Miocene a locus of vigorous coral growth, has been essentially devoid of any reefal development since the Messinian Salinity Crisis, during which the Mediterranean desiccated or at least became hypersaline (Brachert et al., 1996). It later refilled with cryospheric Atlantic middle water, thus displacing its warm water fauna with one of cold water, that has never been fully displaced even though the Mediterranean has warmed since. In the Plio and Pleistocene, and in some places also in the Holocene, *Cladocora caespitosa* formed sizeable (meters thick) banks (Aguirre and Jimenez, 1998). Algal-built hardgrounds (the coralligène, Bosence, 1985a) and *Cladocora* banks presently occur, but are at best analogues to more ancient, but not equivalent to recent W-Atlantic reefs.

The end-Miocene, early Pliocene faunal crisis in the eastern Atlantic left an isolated but highly diverse fauna with mainly Indo-Pacific species in the western Atlantic that was fully isolated with the formation of the Panamanian land bridge in the lower Pliocene (~3.5 Ma = million years ago; Collins et al., 1996). During the period of 6–1 Ma, the Indo-Pacific fauna was progressively reduced by a relatively slow step-down extinction and replaced by pulses of modern Caribbean fauna. Seventeen of 41 genera living in the Caribbean in the Pliocene became extinct, 11 of these genera continued to exist in the Indo-Pacific. No new genera originated and, with the exception of *Pocillopora* which disappeared again, no species immigrated (Budd and Wallace, 2008). Prior to this turnover, shallow areas were dominated by *Stylophora* and *Pocillopora*. One of the most iconic species of the Caribbean coral fauna, *Acropora palmata*, is first reported from Costa Rica (Quebrada Chocolate Formation) about 3.6–2.6 Ma (McNeill et al., 1997). *A. palmata* was rare at the beginning of its rise. *A. cervicornis*, however, commonly cooccurred with *Stylophora* in several late Pliocene formations (e.g., in Costa Rica, Jamaica, and Curaçao; Budd and Wallace, 2008). Several other *Acropora* (two of the subgenus *Isopora* which presently only occurs in the Indo-Pacific) had existed in the Caribbean but had all disappeared during the last extinction pulse around 2 Ma. Molecular analyses have shown that several traditional families of coral may be polyphyletic (e.g., Faviidae, Mussidae), and may be even many genera (e.g., *Montastraea*, *Favia*, *Scolymia*). A distinct clade in Atlantic members of the Faviidae and Mussidae suggests that the relationship between Atlantic and Indo-Pacific corals may indeed not be very close and divergence could predate final closure of the Central American Isthmus in the Pliocene to as early as the Eocene. Nine of the 27

genera of reef-building Atlantic corals belong to this previously unrecognized lineage, which probably diverged over 34 Ma (Fukami et al., 2004) (Figure 1).

### Loss of long-term ecological stability

Remarkable ecological stability has been observed in Caribbean coral assemblages throughout the Pleistocene and Caribbean coral reefs exhibit a clear zonation pattern throughout the region (Geister, 1983). It has been shown that coral community structure on Caribbean coral reefs reassembled after global sea-level changes in similar ways throughout a 500-ka interval (Pandolfi and Jackson, 2006). Six common coral species (*A. palmata*, *A. cervicornis*, three *Montastraea*, and *Diploria strigosa*) dominated the reef-building episodes. While not unique to the Caribbean, this is the longest demonstrated such interval of community stability. Similarly, Pleistocene community recurrence patterns were found in New Guinea (Huon Peninsula) over 115 ka (Pandolfi, 1996). In the Holocene, community stability has been demonstrated in the Caribbean (Aronson et al., 2004) and Brazil (Leao and Kikuchi, 2005). However, in stark contradiction to the situation in the Pacific, this persistence of community structure has recently been lost throughout most of the Caribbean by the almost region-wide demise of the *A. palmata* zone and equally dramatic reduction of *A. cervicornis* (Pandolfi and Jackson, 2006). Also in Brazil, community patterns and coral density that have shown relative stability on millennial scales have recently changed (Leao and Kikuchi, 2005).

### Types of reefs and frameworks

The W-Atlantic/Caribbean region exhibits reef growth in all the classic carbonate sedimentological settings (Schlager, 2005; Hine et al., 2008): ramp (W-Florida, NE Yucatan), unrimmed shelf (Yucatan, Brazil), attached rimmed shelf (SE Florida and Florida Keys, Cuba, Belize), and rimmed shelves on unattached (or isolated) platforms (Bahamas banks, Chinchorro, Belize banks, etc.). A specialty of Atlantic rimmed shelves is coral reefs often cooccurring and alternating with grainstone shoals (frequently ooids, i.e., Bahamas and Yucatan).

In the shallowest regions of the shelf, typical *fringing reefs* (e.g., around St. Croix, Vieques, Lesser Antilles, Cayman Islands, Jamaica, Roatan, etc.) or *bank-barrier reefs* (such as developed in the Florida Keys or the SE Puerto Rico shelf) occur. Many of these fringing reefs are built by *A. palmata* frameworks in situ, although some are not and consist mainly of rubble (see below). Many such structures initiated about 8–6 ka and either continued growing until today or, as in the high-latitude SE Florida continental reef tract, experienced a switch off around 6–4 ka. On the middle shelf, *mid-shelf reefs*, situated at a depth level intermediate between shelf-edge and fringing reefs, are reported from many Caribbean localities (Puerto Rico, Vieques, Florida, Cayman, etc.). Blanchon et al. (1997) explained mid-shelf reefs at Cayman as a result of stepped Holocene sea-level change, i.e., periods

**Western Atlantic/Caribbean, Coral Reefs, Figure 1** (a) *Acropora palmata*, an iconic species for the Caribbean coral fauna (here at Lee Stocking island, Bahamas), has recently experienced significant die-back throughout its range (b) long-term ecological stability throughout the Pleistocene (outcrop in Curacao), (c) stromatolites can form small fringing reefs in the Bahamas or subtidal structures, such as these at Lee Stocking island, Bahamas. Measuring stick = 1 m. The stromatolite with the stick shows artichoke-like leaves, (d) rubble is an important constituent of Caribbean reef frameworks and now all that is left of the former *A. palmata* zone throughout much of its range, (e) islands on the northern Caribbean banks do not have fringing reefs. Shown is Lee Stocking Island on the Great Bahama Bank, the only area of shallow *A. palmata* reef is shown in a circle, the area of subtidal stromatolites within a dotted polygon, and the trend of the mid-shelf reef (at about 10 m depth) with a dashed line. (f) The western end of Roatan (Bay Islands, Honduras) with a typical fringing reef and three offshore bank reefs to the south.

of unusually rapid and then slowing sea-level rise. The realism of this sea-level assumption (as that of many others) is, however, being debated (Hubbard et al., 2008; Blanchon et al., 2009) and mid-shelf structures can be found at variable depth and with variable morphology (Banks et al., 2007; Hubbard et al., 2008), making their explanation purely by sea-level difficult since antecedent topography may have also played a role. *Shelf-edge reefs* are a typical feature throughout the Caribbean and have been described in detail from Barbados (Macintyre, 1988), Florida (Lighty et al., 1978, Banks et al., 2007), St. Croix, the Lang Bank, and Puerto Rico (Hubbard et al., 1990, 2008). They are typically built by *A. palmata*, are situated at depths around 20 m, initiated around

12–10 ka, and flourished until ~8 ka. Tracking rising sea level, they then stepped back throughout the Caribbean to form the wide variety of shallower shelf reefs. In Belize and Mexico, the Caribbean also has one of the world's biggest *barrier reefs*, a largely structurally controlled feature where reef development is guided and determined by fault lines (Purdy et al., 2003), lowstand karst topography (Purdy, 1974), and paleo-river beds (Esker et al., 1998). Other large barrier reefs exist in the Bahamas at Andros, in the Turks and Caicos, Venezuelan off-shore banks, etc.

Deep, submerged *bank reefs* occur in the Gulf of Mexico (half a dozen banks of which the Flowergarden banks are the most famous, Schmahl et al., 2008), where they are associated with salt diapirism, on the Nicaragua rise, and

in Brazil (Leao et al., 2003), where they often consist of bedrock (older limestones or crystalline basement). Unusual, bank-like, deep reefs also occur off SW-Florida, such as the carbonate banks of the Florida Middle Grounds and a drowned dune/coastal spit complex at Pulley ridge (Jarrett et al., 2005). These deep banks are home to unique, and frequently dense, coral assemblages (Hine et al., 2008).

Several reef types unique to specific Atlantic region exist. *Outlier reefs* in the Florida Keys Reef Tract (Lidz et al., 2008; Hine et al., 2008) are Pleistocene reefs situated on an upper-slope terrace, separated from the present shelf edge with its shelf-edge reefs by a well-developed trough. Outlier reefs form a discontinuous and drowned (surfaces at around 10 m below MSL), largely parallel tract to the major present reef trend on the shelf edge. The outliers comprise a stacked sequence of reefs from MIS 5c at the base to 5b and 5a at the contact to Holocene overgrowth and Lidz et al. (2008) consider them testament to optimal platform margin settings for reef growth during 5c and later times. *Algal cup reefs* occur in Bermuda. They are somewhat reminiscent of the Brazilian Chapeiros (mentioned below) inasmuch as the cup reefs can also take a mushroom-shaped appearance. The tops are made by calcareous algae and can have a raised rim and a slightly deeper interior. They are mostly built by calcareous algae, the gastropod *Dendropoma irregulare* and *Millepora* spp. (Ginsburg and Schroeder, 1973). *Algal ridges* occur throughout the Lesser Antilles that are built by several thousand years of algal growth (Adey and Burke, 1976) and off Cozumel, *coralline algal microatolls* occur (Boyd et al., 1963). *Chapeiros* in Brazil are pinnacle reefs made of Holocene reef limestone that consist of isolated narrow pillars that expand on the top to take a mushroom-shaped appearance (Leao et al., 2003). These reefs can be 5–25 m high and have diameters of 5–50 m at their tops and are mainly built by coral. This type of reef is restricted to the Abrolhos reef complex in southern Bahia State, where a wide variety of morphologies of isolated and coalescent Chapeiros exist. On many other Brazilian reefs, most particularly close inshore, substratum for coral growth is frequently on the former beachrock, indurated dunes, or bedrock (igneous or carbonate). This situation is reminiscent of high-latitude reefs in the Indo-Pacific, with corals in SE Africa and SE Australia carpeting indurated sand dunes and beachrock ridges. *Stromatolites* are microbialites that are common and attain large sizes along the Exuma margin in the Bahamas. Modern stromatolites, which are layered sedimentary rocks formed by sediment-trapping microbial mats, are rare and best documented from W-Australia (Shark Bay) and the Bahamas (Reid et al., 1995). The Bahamian stromatolites can be domal, molar shaped, or elongate and have some leaf-shaped structures that are reminiscent of Precambrian stromatolites. At Stocking Island and Highbourne Cay in the Bahamas, regular small fringing reefs are dominated in their backreef areas by stromatolites and toward the beach by thrombolites (Macintyre et al., 1996; Reid et al., 1999; Andres et al., 2009). These stromatolites are <1 ka of age and grow on a Holocene reef that was killed by sediment trapping in the lagoon after the emergence of

the reef edge, built by coralline algae. These Bahamian stromatolite reefs are unique, their only known Pacific counterparts in Shark Bay (Playford and Cockbain, 1976) or in Tikehau lagoon (Sprachta et al., 2001). The latter, however, occur in a high-nutrient setting, while the Bahamian stromatolites occur in nutrient-poor setting.

In deep water, off Florida, the Bahamas and in the Gulf of Mexico, well-developed *Lithohierms* occur (Neumann et al., 1977; Roberts, 1992). These are defined as deep-water mounds formed by successive episodes of submarine lithification of sediment which may contain carbonate skeletal debris and are often locus of tropical reefal assemblages (Messing et al., 2008). In the Gulf of Mexico, many consist of authigenic carbonates precipitated in conjunction with bacterial utilization of hydrocarbon gases and crude oil produces (Roberts, 1992). Also, *deep-water reefs*, built among others by the corals *Lophelia pertusa*, *Oculina varicosa*, and *Madrepora oculata*, can form significant three-dimensional carbonate buildups in Florida, the Bahamas, and the Gulf of Mexico (Messing et al., 2008).

### Similarities and differences to Indo-Pacific reefs

While the same nomenclature is used for reefs in the Caribbean/western Atlantic, there can be marked differences in the structures of reefs between the two regions. While in both oceans shallow reef zones are characteristically dominated by the genus *Acropora*, the difference in growth form between Atlantic and Indo-Pacific members of this genus causes differences in the structure of frameworks. Caribbean reefs built by *A. palmata* can differ from those of the Indo-Pacific by consisting of more or less dense stands of *Acropora* trunks that get filled in by debris (usually broken *A. palmata* branches) later to get cemented. Hubbard et al. (1998) described Caribbean reefs as “more a garbage pile than an in place assemblage of corals cemented together in a rigid framework,” as is more usually observed in the Indo-Pacific (Hopley et al., 2007). Indeed, some Caribbean reefs are largely devoid of reef builders in situ and consist almost exclusively of tossed debris, without much living veneer (e.g., the Grand Cayman fringing reef; Blanchon et al., 1997; sections of the Vieques fringing reef, Rasser and Riegl, 2002). It appears that rubble binding by red algae and sponges is more efficient in the Atlantic than in the Indo-Pacific (Rasser and Riegl, 2002). The importance of coral facies (branching vs. massive) is discussed by Gischler (2008) and Hubbard et al. (2008) – interestingly, massive facies appear to have accreted almost as rapidly as the branching *Acropora palmata* facies.

Neither the Florida Keys nor any of the islands on the major banks (Great and Little Bahama Banks, Caicos Bank, Turks Bank) are surrounded by well-cemented and continuous fringing reefs that are so typical for many Indo-Pacific atolls and carbonate banks (such as the Great Barrier Reef, island on the Red Sea banks, Maldives and Chagos banks, etc.) and are also well developed in the southern and eastern Caribbean (Bay Islands, ABC

islands). The relatively high-latitude setting of the northern Caribbean carbonate banks (Florida, Bahamas) puts them under the influence of N-American weather systems, most particularly, cold fronts (Roberts et al., 1982). Thus, alternations of strong heating in summer and strong episodic cooling of the shallow bank waters affect reef growth. On the banks, reef growth is therefore concentrated where islands shelter the reefs from the direct influence of bank waters (Ginsburg and Shinn, 1994). This is not observed on many of the banks in the more tropical Caribbean (Grovers, Lighthouse Turneffe, Chinchorro) that are indeed surrounded by luxurious reef growth.

Unique reef-like accumulations of branching corals (*Porites divaricata*) and branching algae (*Neogoniolithum strictum*) occur around Rodriguez and Tavernier Key off Key Largo in Florida (Turnel and Swanson, 1976; Bosence, 1985b). The windward edges of these banks are good examples of constratal reef building (Insalaco, 1998) inasmuch as the corals and algae form a loose framework that gets filled by muddy sediment. Although indicated by the mounding morphology, the presence of this framework is visible primarily in core but not at the sediment surface, other than by a localized higher density of branching corals and algae.

A major difference in the Indo-Pacific is the absence of evidence for an early Holocene sea-level overshoot in the Caribbean region, although it has been demonstrated in Brazil (Leao et al., 2003; Gherardi and Bosence, 2005), and the most commonly used sea-level curves show a rapid rise ( $>5\text{--}6\text{ m/ka}$ ) until about 8–6 ka, when it slowed to about 1 m/ka while ascending to today's level (Toscano and Macintyre, 2003; Hubbard et al., 2008). Throughout the Pacific, there is clear evidence of an early-to mid-Holocene temporary sea-level highstand of about 3 m, centered at 4 ka (the Brazilian record suggests a maximum of nearly +5 m at ~5 ka, with subsequent decline to today's level; Leao et al., 2003). The overshoot (generally ascribed to earth rheology) is documented in raised reefs, raised intertidal notches, or raised intertidal benches throughout the Pacific basin. The Caribbean region does not display any unequivocal such features, but Brock et al. (2008) used morphological features of northern Florida Keys patch reefs in combination with raised beach ridges to infer such an overshoot also for the Caribbean region.

## Conclusion

- Coral reefs in the Atlantic/Caribbean differ from those in the Indo-Pacific with regard to fauna as well as aspects of reef framework formation.
- The Atlantic coral fauna began its evolution prior to the closing of the isthmus of Panama, but fully diversified only afterwards.
- Remarkable ecological continuity of Pleistocene coral community organization has recently been lost.
- Several types of reefs unique to the Atlantic/Caribbean exist (stromatolitic fringing reefs, Chapeiroes, algal cup reefs, outlier reefs).

- Fringing reef and island development on the largest Caribbean banks (Bahamas banks, Florida Keys) are frequently different than in the Indo-Pacific due to relatively high-latitude position, but more comparable within the truly tropical belt (Belize, Venezuela, etc.).
- No Holocene raised reefs known from Caribbean region, only in Brazil signs of early Holocene highstand.

## WESTERN AUSTRALIAN REEFS

Lindsay B. Collins  
 Curtin University of Technology, Bentley, WA

## Synonyms

Reefs; Western Australia

## Definition

Wave resistant structures built primarily by coral growth.

## Introduction

Situated in the eastern Indian Ocean along the western continental margin of Australia, coral reefs extend from the tropical Kimberley coast in the north to the temperate southwest (Figure 1).

This latitudinal climatic gradient places reefs in a setting likely to become increasingly significant as a natural laboratory when predictions of global climate change are considered. The relatively small human population along several thousand kilometres of coast (44% of the Australian coastline) limits anthropogenic impacts from a largely desertic coastal hinterland bordering the continental shelf. Coral reefs include fringing reefs such as the Ningaloo Reef (at 280 km long, the world's longest fringing reef), mid-outer shelf reefs such as the Houtman Abrolhos reefs, the southernmost reefs in the Indian Ocean, and isolated reefs such as the Rowley Shoals and Scott Reef as some of the better known reefs, but there are many other poorly known and remote systems in the region.

## Regional oceanography

Three oceanographic and biogeographic provinces (Figure 1) present along Australia's west coast are: the Northern Australian Tropical Province (11–22°S), the

Western Coast Overlap Zone (22–32°S), and the Southern Australian Warm Temperate Province (south of 32°S). This regional oceanography is influenced by the South Equatorial Current, at 5–15°S latitude, driven by easterly trade winds, and the Indonesian Throughflow, which floods the North West Shelf with warm, low salinity water, resulting in sea levels in the tropics being 0.5 m higher than along the southern coast of Australia. With higher tropical sea levels, the formation of a north-south pressure gradient induces a weak easterly flow of central Indian Ocean subtropical water toward the Australian coast between 15–35°S (Pearce and Griffiths, 1991). This easterly flow is deflected south by the coastline, eventually contributing to the Leeuwin Current, a warm low salinity current which flows from the Indonesian Throughflow, southward along the adjacent shelf in winter. The Indonesian Throughflow delivers larvae of both Pacific and Asian reef species southward, and the Leeuwin Current is an important control on southward larval delivery, whilst suppressing upwelling (Hatcher, 1991). Tidal range and cyclone frequency decrease from north to south. The North West Shelf is cyclonic and tidally dominated, with a mean spring range from 9.2 m in King Sound to 1.7 m at Ningaloo Reef (Harris et al., 1991). Both Scott Reef and Rowley Shoals have semi-diurnal tides with a spring range of 4.5 m. At the southerly limits the coral growth reefs are microtidal (1 m) and swell wave dominated with low cyclone frequency (1 per 4 years).

## Reef morphology

Studies of Australian reefs have been dominated by work on the eastern seaboard and the Great Barrier Reef (see Hopley et al., 2007), but reefs of the western continental margin of Australia and its bordering carbonate ramps remain relatively unknown. Coral reefs of Australia's western margin include isolated oceanic atoll-like reefs (Ashmore Reef, Seringapatam and Scott Reefs, Rowley Shoals); island-associated shelf reefs and fringing reefs of the Kimberley coast and Dampier Archipelago; Pilbara reefs (Barrow and Montebello Islands); Ningaloo Reef, a fringing reef adjacent to the North West Cape, and the mid- outer shelf Houtman Abrolhos carbonate platforms and reefs (Collins et al., 1993a, b, 1997, 2009).

## Mid-outer shelf reefs: the Houtman Abrolhos

Between latitudes 28–29.5°S the open, low-gradient shelf is interrupted by a 150 km long, discontinuous rim, whose seaward margin is 8–10 km east of the shelf/slope break near the 100 m isobath. The emergent rim consists of three platforms (Pelsaert, Easter and Wallabi platforms) separated by channels up to 40 m deep. Each platform rises abruptly some 40 m above a flat shelf, and culminates as reef flats and low islands. Submerged banks lie to the north and south of the platforms along the same trend. The three platforms differ geomorphologically but a windward reef, leeward reef, and lagoon with a central platform is distinguishable in each case. Both the central

**Western Australian Reefs, Figure 1** Distribution of Western Australian Reefs. Note position of Northern Australian Tropical Province (white), Southern Australian Warm Temperate Province (dots) and Western Coast Overlap Zone.

platforms and leeward reefs are expressed as small islands of various types, whereas windward reefs are wave-swept. The central platforms are the last interglacial ones in age, whereas the windward and leeward reefs are Holocene (Eisenhauer et al., 1993; Collins et al., 1993a, b; Zhu et al., 1993). The islands generally rise only 3–5 m above sea level. Extensive ‘blue-hole’ terrains and reticulate reefs occur at the eastern parts of the platforms and Holocene sand sheets have developed in both the windward and leeward lagoons (Wyrwoll et al., 2006). Central platform islands are surfaced by dense, calcified limestones, while subparallel ridges of coral rubble characterize leeward (eastern) islands.

The Houtman Abrolhos region is located within the Western Coast Overlap Zone and biotic transition (Morgan and Wells, 1991). It is characterized by the gradual replacement of a tropical fauna in the north by a predominantly temperate fauna in the south, as reflected in a variety of shelf and reef biotic elements, including corals, macroalgae, molluscs, echinoderms and fishes. Coral faunal communities are highly diverse; 184 species and 42 genera are recorded

(Veron and Marsh, 1988). The number of genera is much higher than for other ‘high latitude’ coral reefs (e.g., the Solitary Islands; Kure Atoll; Bermuda Reefs). *Acropora*, which is missing or very rare on many ‘high latitude’ reefs is the dominant coral. Although there are substantial numbers of temperate species and Western Australian endemic species the fauna at the Houtman Abrolhos is, on the balance, essentially tropical, and is generally considered to be at the southern limit in Western Australia of the tropical biota. Forty metres of Holocene reef buildup has occurred yielding high precision reef growth and sea level records for the Holocene and the last interglacial reefs (see Eisenhauer et al., 1993; Collins et al., 1993a, b).

#### Ningaloo fringing reef

Situated close to North West Cape and Cape Range, this fringing reef complex consists of a narrow reef crest, which is emergent at low water, with well-developed spur and groove morphology present on most outer reef slopes; complex multiple developments of spur and groove are also present. The reef crest is backed by a reef flat

(usually <150 m wide), which has robust coral communities, as well as coral rubble veneers, and deep grooves flooded by sandy sediment which shallow and broaden landward. A shallow (0–4 m water depth) lagoon of a width of 1–5 km consists of rock pavements with sparse corals, and mobile sandy substrates with scattered coral communities. The lagoon shore is sandy or consists of rock pavements vegetated by macroalgae, and low cliffs and emergent platforms of the last interglacial reef limestones. Reef development is interrupted by passes and transverse channels, up to 200 m wide, which are sites for water exchange between the lagoon and the adjacent shelf. Highest coral cover and reef development occur along reef passes and in the lagoon, while the outer reef slopes do not host such rich coral communities.

Ningaloo Reef lies at the northern extremity of the Western Coast Overlap Zone. Ningaloo reef corals have strong Indo-Pacific affinities, and 54 genera and 217 species of hermatypic corals have been identified (Veron, 1995). Coral cover reaches to 40% on the swell-exposed reef front, but the outer reef slopes lack rich coral communities and coralline algae are significant. Behind the reef crest coral cover varies from 5% to 40%, with the strongest reef development in the passes and in the lagoon.

The relationship between the Holocene and the last interglacial phases of reef development is clearly shown from seismic, core data, and outcrop (Collins et al., 2002). The stratigraphic cross-section for the northern (Tantabiddi) reef is based on short cores in the lagoon and in front of the reef. These core data are consistent with cross-reef seismic lines, and indicate that Holocene reef growth recolonized the Tantabiddi Terrace (last interglacial reef) near its submerged, seaward margin, and at ca. 18 m is relatively thin (e.g., when compared to the 40 m of Holocene growth at the Houtman Abrolhos). The last interglacial reef is widespread, comprising the Tantabiddi Terrace onshore and extending beneath the lagoon of the contemporary reef. The greater southerly extent (to 33°S, at Margaret River; Playford, 1997) and more vigorous development of last interglacial reef is considered to represent a stronger Leeuwin Current at that time.

The Holocene transgression in the Ningaloo reef tract reached a height of +1 m some 4000 years ago, (Wyrwoll et al., 1993) compared to the last interglacial high stand of +4 m. The Holocene reef crest grew along the seaward margin of the last interglacial reef system, so its vertical growth potential was limited by the elevation of the reef system it colonized.

### Reefs of the Pilbara coast

Reef systems in this region are the Dampier Archipelago, close to the coast, and offshore island-associated reefs at the Montebello and Barrow Islands. The Dampier Archipelago is high in coral diversity but is subject to extreme environmental conditions such as macro-tides, cyclones and storms as well as fluctuating turbidity and warming temperatures in an area of growing industrialization.

The offshore islands form a complex archipelago of over 250 small islands with a mainly tropical flora and fauna.

### Reefs of the Kimberley coast

Reefs along the Kimberley coast and shelf lie within a major hydrocarbon province and are essentially of two types; isolated offshore reefs and fringing reefs. Along the deeply embayed, macrotidal Kimberley coast is an extensive chain of fringing reefs which are very poorly known, but there are indications that they are of international significance and are in need of intensive study (Wilkinson, 2008). The most significant offshore reefs are the Rowley Shoals, and Scott Reef. These reefs and small carbonate platforms formed along an old Miocene continental margin; during the Miocene the Scott Reef/Rowley Shoals platform formed a narrow continental shelf, and the reefs have persisted there despite rapid subsidence of the shelf edge since the mid-Miocene. Whilst the offshore reefs are subject to cyclones and bleaching (Smith et al., 2008; Heyward et al., 1997) due to their isolated position some of the reefs are regarded as amongst the most pristine environments remaining in the world (Wilkinson, 2008).

The Rowley Shoals (Mermaid, Clerke and Imperieuse Reefs) were described as the most perfect morphological examples of shelf atolls in Australian waters (Fairbridge, 1950). The three shoals have similar dimensions, shape, orientation and distance apart, and all rise from the distal ramp of the North West Shelf at latitudes 15–17°S. From northeast to southwest the reefs rise from progressively shallower depths on their landward sides; Mermaid Reef from 440 m, Clerke Reef from 390 m, and Imperieuse Reef from 230 m. Each atoll (length range 15–17 m, width range 7–9 km) has north-south orientation, is pear-shaped with the narrower end to the north, and has a reef which encloses a single central lagoon which is ovoid and relatively deep in Mermaid Reef, but becomes increasingly shallow and segmented in Clerke and Imperieuse Reefs. About two thirds of the way up its eastern side, each system has a narrow passage (or passages), through which tidal flushing and sediment exchange occur.

Mermaid Reef has, on its western side, an outer reef flat (0.5 km wide), which is exposed at low tide, and a back reef of similar width, backed by 1 km wide sand flat. The eastern reef is only 0.6 km wide and the sand flat is absent. The western outer reef slope has well-developed spur and groove, the outer reef has coralline algae and slow-growing corals, while the back reef flat has a cover of living and dead coral and algal turf (Berry and Marsh, 1986). At Clerke Reef the shallow (<10 m) lagoon is segmented into three parts by sand sheet development. Imperieuse Reef has a lagoon partitioned into three basins by sand sheet development but the two along the eastern edge are deeper than the larger, central basin which is extensively infilled by a meshwork of coral growth, composed of flat-topped coalescent reef with intervening sand-floored depressions. The coral assemblages described for

Scott Reef by Done et al. (1994) are also recorded at Rowley Shoals. Differences in reef morphology, hydrodynamic exposure and ponding are reflected in the assemblages. Seismic studies indicate Holocene reef thicknesses of 18–36 m based on the difference in the depth of the last interglacial reflector in the lagoon (36 m below sea level in Mermaid Reef, but only 18 m below sea level in Imperieuse Reef; Collins, 2009) suggesting that differential tectonic subsidence since the last interglacial has controlled the accommodation space available for Holocene lagoon infill, which at Imperieuse Reef was only 50% of that available at Mermaid Reef, and this is an important control on the differential amounts of lagoon infill observed between the two reefs.

### Reefs and shoals of the Sahul Shelf, Northern Australia

Marginal to the Sahul Shelf and close to the Timor are a series of isolated reefs (Seringapatam, Ashmore Reef; Cartier Island) and shoals (Karmt, Big Bank and Echo Shoals; Heyward et al., 1997). The shoals formed a string of islands seaward of the palaeo-coastline and were drowned in the last 20,000 years (Lavering, 1993) becoming submerged to below the euphotic zone, terminating carbonate production by photosynthetic organisms. Thereafter bank growth has been by *Halimeda* accumulation, which has apparently dominated since the Late Pleistocene (Heyward et al., 1997).

### Summary

Coral reefs in Western Australia are rich in marine biodiversity, and are ranked second in the world in terms of endemism (Wilkinson, 2008). Whilst industrial impacts will increase in the future, reefs in this vast area are usually far from population centers. Though some are close to the coast, there is low terrestrial runoff because of the dry and arid climate. Whilst there are challenges for research, monitoring and management due to remoteness and the vast distances involved, research and management planning are increasing commensurate with international recognition of the region's importance.

## WESTERN INDIAN OCEAN

Lucien F. Montaggioni  
 University of Provence, Marseille Cedex 3, France

## Definition

The Western Indian Ocean is defined as the tropical region bounded by the Gulf of Aden on the north, by eastern Africa on the west, by the Chagos and Maldivé Archipelagoes on the east and by latitude 26°S on the south. The ocean washes the African coasts from Somalia to south Mozambique, Madagascar and a myriad of high- and low-lying islands, in particular, the Seychelles.

## Reef sites

The coral reef areas in the Western Indian Ocean (WIO) are latitudinally distributed between about 2°N and 26°S. The southernmost coral communities that grow along the South African coasts at 27°50'S are not regarded as true coral reefs.

Fringing reefs are widespread, especially along the eastern African coasts from Somalia, Kenya, Tanzania to Mozambique, around the granitic Seychelles Islands (Mahé, Praslin), the Mascarene (Réunion, Mauritius, Rodrigues) and the Comoro Islands and on the northwestern sides of Madagascar. Barrier-like structures are restricted to Rodrigues and Mayotte Islands, the southeastern coast of Mauritius, northwestern and southwestern coasts of Madagascar. Atolls and/or low-lying coral islands (reef platforms) form the carbonate Seychelles (e.g., Aldabra, the Amirantes

and Farquhar Islands), Agalega Islands and most of the so-called French Scattered Islands (Tromelin, Europa, Juan de Nova, Bassas da India). Partly to totally submerged bank reefs include Soudan, Glorieuses, Cargados Carajos (Saint Brandon), Nazareth and Saya de Malha, located north to northeast of Madagascar and Mauritius. Except for Madagascar and the granitic Seychelles regarded as continental remains, the core of all these islands is likely to be volcanic in origin (Stoddart, 1971). Most of the data on the WOI reef attributes were gained from the fringing and barrier systems. Little is known about atolls, reef platforms and bank reefs.

## Main attributes of reef communities

The WIO has a high generic coral diversity. The number of genera is the highest in the Seychelles areas (>50) and decreases with increasing latitude as a response to decreasing sea surface temperature. This number ranges between 30 and 35 at the southern most part of Mozambique (about 24°S) and at the entrance of the Gulf of Aden (about 12°30'N). Four major groups of coral assemblages have been identified according to changes in wave exposure, light level and depth (Faure, 1982).

Group I refer to coral assemblages living along the deeper fore-reef zone at depths greater than 30 m. These assemblages are dominated by the encrusting *Echinophyllia* and *Leptoseris*. Group II include the communities inhabiting the intermediate and upper fore-reef zones. The intermediate parts (<30 to about 10–15 m) are composed usually of encrusting or foliaceous forms including *Pachyseris*, *Echinopora*, *Cyphastrea*, *Turbinaria*, *Montipora* and a variety of massive faviids (*Favia stelligera*, *Favites halicora*). The upper parts of outer slopes (<10 m) are usually made up of tabulate corals (*Acropora hyacinthus* group; *Acropora tenuis*), massive *Porites* replaced upwards by robust branching corals (mostly *Acropora robusta* or *A. humilis* groups; *Pocillopora verrucosa* and *P. eydouxi* groups; *Stylophora*) and the hydrocoral *Millepora platyphylla*.

Group III is typified by reef-crest and reef-flat coral communities. At high water-energy settings, reef-crest and outer reef-flat zones dominantly exhibit those robust acroporid forms colonizing the uppermost fore-reef slopes, together with *Montipora tuberculosa*, *Acropora mammilata* and massive faviids (*Favites melicerum*, *Favia stelligera*). In less agitated areas, corals mainly include arborescent branching *Acropora muricata*, *A. hemprichi*, gracile *A. variabilis*, *Galaxea fascicularis* associated with domal *Porites lutea*, and *Montastraea curta*. In inner reef-flat zones, the prominent corals are arborescent *Acropora muricata*, *A. palifera*, *A. pulchra*, tabulate *A. cytherea*, with *Pocillopora damicornis*, *Pavona divaricata*, *Porites solida*, *P. nigrescens*, *P. andrewsi*, *Synarea iwayamaensis* and *Goniastrea retiformis*.

Group IV refers to coral communities inhabiting backreef and lagoonal environments. These are dominated

by forms adapted to low water energy conditions and represented by *Acropora muricata*, *A. hyacinthus* group, *Pavona danai*, *P. divaricata*, *P. varians*, *Porites lutea*, *P. solida*, *Synarea iwayamaensis*, *Goniastrea pectinata*, *Leptastrea purpurea* and *Lobophyllia corymbosa*.

Most reefs possess non-elevated coralline algal pavements. Typical algal ridges locally with an elevation of about 1 m, have been described from Rodrigues, Caragos Cargados Banks and the granitic Seychelles. The development of these structures within the region is regarded as controlled by the intensity of southeast trade winds (Rees et al., 2005).

### Sediment components and carbonate production

The major compositional characteristics of surficial sediment assemblages from the WIO reefs can be summarized as follows (Montaggioni and Braithwaite, 2009).

In most fringing reefs, a basic distinction can be made between and within the different environments in terms of the coral content. The fore-reef sites contain highly variable amounts of coral particles (2 to about 50% of the total sediment). By contrast, reef flats and proximal back-reef settings have coral contents not lower than 20% and approximating to 60%. These values partially reflect the high cover rates of coral assemblages (30–80%). On barrier reefs and atolls, there is a distinct separation between outer reef rims and lagoonal environments in terms of coral composition. In most lagoonal sheets of both barriers and atolls as in Mayotte, coral is a secondary component, forming 3 to less than 15% of detritus on an average. The scarcity of coral detritus clearly is indicative of local impoverishment in coral coverage (less than 10% of the substrate) except in portions adjacent to patch reefs and coral buildups with high coral coverage. Similar to corals, coralline algae generally exhibit higher abundance in sediments deposited close to reef margins and coral patches. Irrespective of reef types, the amount of coralline fragments was found averaging 5–15 to 30% of the total sediment, from deeper fore-reef to back-reef zones as observed in Réunion, Mauritius, Rodrigues and Mahé Islands. By contrast, lagoonal environments generally exhibit low concentrations in corallines, averaging 0 to around 4% of the sediments on most barriers and atolls. Debris from green algae *Halimeda* vary considerably in abundance throughout the region. Their amount ranges between 0% and 90% of the total sediment, reaching the highest values in the granitic Seychelles and are absent from high-latitude reefs of southern Mozambique. The proportions of molluscan bioclasts average 10–25% of the carbonate material along the fore-reef slopes and in the reef-flat environments. In back-reef and lagoonal settings, molluscs increase markedly in abundance (25–45%). In many reefs, benthonic foraminiferal detritus dominates along the fore-reef slope, representing 17 to approximately 60% of the total sediment grains. By contrast, their amount declines markedly in reef-flat, back-reef zones, and lagoons not exceeding 2–20% in all studied sites.

Estimates of calcium carbonate regionally deposited by oceanic island reefs over the last 5,000 years are approximately 217 Gt, expressing a flux of  $4.3 \times 10^{11}$  mol yr<sup>-1</sup> CaCO<sub>3</sub> into sediments. Assuming that each mole of CaCO<sub>3</sub> releases 0.6 mol of CO<sub>2</sub> to the atmosphere, about  $2.6 \times 10^{11}$  mol yr<sup>-1</sup> CO<sub>2</sub> are estimated to have been transferred by WIO reefs to the atmosphere during the optimal phase of reef growth (9,000–4,000 years ago), representing 57 Gt CO<sub>2</sub>. These values do not include carbonate production in the early and late Holocene and contributions from eastern Africa and submerged bank reefs. As such, the volumes of CaCO<sub>3</sub> accumulated and CO<sub>2</sub> released by the whole WIO reefs may effectively be doubled (Rees et al., 2005).

### Reef growth history during the last deglaciation

A detailed regional reconstruction of reef growth history in relation to the rise in sea level over the last 18,000 years has been provided based on reef coring (Réunion, Mauritius, southwestern Madagascar, Mahé, Mayotte), submersible observations and sampling of fore-reef slopes at Mayotte (Camoin et al., 2004).

An earlier fringing reef generation developed at around 20,000–18,000 years BP along the Mayotte foreslopes when sea level was about 110–120 m below its present position. A second reef tract dated at 13,600 years BP occurs at a present water depth of 90 m. It was drowned at 13,500 years BP (Meltwater Pulse 1A). A third reef generation at present submerged at 60 m depth is regarded as formed at around 12,000 years BP. However, there is no direct evidence to support a well-defined surge at about 11,500 years BP (Meltwater 1B). Throughout the region, modern reefs appear to have started to grow between 9,000 and 8,000 years BP. Rates of vertical reef accretion range between 0.9 mm yr<sup>-1</sup> and 7 mm yr<sup>-1</sup>. The reconstructed sea-level curves reflect a rapid rise in sea level at about 6 mm yr<sup>-1</sup> from 10,000 to 7,500 years BP, followed by a marked slowing to 1.1 mm yr<sup>-1</sup>. Sea level reached its present position by 3,000–2,500 years BP.

### Emerged reefs and related features

Numerical predictions assume that there should be a mid-Holocene high stand around 5,500 years BP in the WIO. However, the only robust evidence for mid to late Holocene higher sea-levels to date comes from 2,000 to 3,700 year-old coral and vermetid encrustations at heights of +0.30 to +2.50 m around Madagascar. The lack of Holocene higher sea stand in the volcanic and low-lying carbonate islands and the granitic Seychelles results probably from the negligible effects of glacial isostatic adjustment (hydro-isostasy) on these areas or from compensation by other mechanisms, in particular active subsidence of volcanic aprons (Camoin et al., 2004).

By contrast, reef remains of Late Pleistocene high sea stands, dated at approximately 120,000 years BP (Marine Isotope Stage 5 e) and locally at 240,000 years

BP (Stage 7) are widely distributed along eastern African coasts (Kenya, Tanzania), Mauritius, Madagascar, Europa, Glorieuses, the granitic Seychelles, Aldabra and nearby islands including Assumption, Astove, Cosmoledo and St. Pierre (Stoddart, 1984). The highest elevation of Stage 5 e-reef terraces above the present sea level ranges between about 10–12 m (Kenya), 5–6 m (Tanzania, Madagascar), up to 8 m (the Seychelles Island Groups) and less than 2–3 m (Mauritius, Europa, Glorieuses), thus reflecting differential geodynamic behaviors.

### Coral paleoclimatology

Several reconstructions of the regional climate variability based on geochemistry of massive *Porites* were presented spanning the last three centuries. In particular, contrary to the global warming trend, the Seychelles record reveal a monsoon-driven cooling of the Western equatorial Indian Ocean since the middle of the nineteenth century (Pfeiffer and Dullo, 2006).

### Summary

The WIO exhibits a great variety of reef types surrounding continental masses and high- and low-lying islands. It is typified by a high coral generic diversity (30 to >50). The genera *Acropora*, *Pocillopora* and *Porites* are the major reef builders irrespective of reef site, while the development of coralline algal ridges remains relatively limited. The modern reefs are likely to have begun to develop regionally from about 9,000 years BP. Over the past 5,000 years, their calcium carbonate production is estimated to have been higher than  $400 \times 10^9$  tons. There is little evidence of Holocene reef remains at elevations higher than present sea level. By contrast, reef terraces

deposited during MIS 7 and 5 e high sea stands are at present exposed in a number of sites throughout the region.

## YONGE, SIR MAURICE (1899–1986)

---

Barbara E. Brown  
University of Newcastle, Newcastle, UK

### Definition

An eminent British zoologist, who led the 1928–1929 Great Barrier Reef Expedition to Low Isles and who, together with other team members, provided some of the earliest insights into the feeding biology, growth and reproduction of reef corals. He was also one of the first scientists to describe the bleaching of corals under natural conditions and to investigate the bleaching process both in manipulative experiments and in the field.

Maurice Yonge was an extremely distinguished marine zoologist whose research interests spanned both molluscan and coral physiology. He completed an undergraduate and postgraduate degree at the University of Edinburgh before beginning postdoctoral research at Plymouth Marine Laboratory on feeding and digestion in bivalves. In 1927 he accepted the leadership of the Great Barrier Reef Expedition and soon after began to assemble his interdisciplinary team for a 13 month stay on Low Isles in the northern Great Barrier Reef. The expedition members were divided into a boat party, a shore party and a physiological party with a geographical party also operating alongside the other activities. The 1928–1929 expedition marked the beginning of modern coral reef science with research focussed on *in situ* relationships between reef growth and environment. The biological outputs provided novel information on coral nutrition, growth and

reproduction and early observations and experimental accounts of coral bleaching while the geographical party produced detailed reef surface mapping at a level which had not been previously achieved.

One of the main conclusions arising from the expedition on experimental work with corals was that they were superbly efficient and voracious carnivores and that their symbiotic zooxanthellae made no significant contribution to their nutrition. Much later, in 1964, Yonge began a collaboration with Thomas and Nora Goreau in which they showed, using autoradiography, the importance of zooxanthellae in the nutrition of the giant clam, *Tridacna*. They later acknowledged that corals too might also benefit from the passage of material from the zooxanthellae to the tissues of the animal host, a fact which had by 1970 been established by a number of other scientists.

Although Maurice Yonge's major interests focussed on the bivalve Mollusca his contributions to coral reef science were highly significant with his papers still being cited by authors today, some 80 years after the initial expedition. He was elected to the Fellowship of the Royal Society of London in 1946 and received the Darwin Medal of the Royal Society in 1968 for his work on the evolution of the Bivalvia. He was knighted in 1968 for his contribution to marine science over a 60 year period of active research and service to the subject.

## ZOOXANTHELLAE

---

Andrew C. Baker  
University of Miami, Miami, FL, USA

### Synonyms

Algal symbionts; *Symbiodinium*

### Definition

The term “zooxanthellae” refers to a paraphyletic group of yellow-brown microalgae, including certain dinoflagellates, diatoms, cryptophytes, chrysophytes (golden algae), and rhodophytes (red algae), that are found in mutualistic symbiosis with a variety of invertebrate and protist hosts. “Zooxanthellae” is a plural noun (singular: zooxanthella) derived from the Greek words *zoo* (animal), *xanthos* (yellow), and *ella* (diminutive): “yellow animal cells.” On coral reefs, vernacular usage almost exclusively refers to the symbiotic dinoflagellates in the genus *Symbiodinium* that are commonly found in certain corals, anemones, jellies, clams, worms, sponges, and other reef organisms.

### Introduction

Zooxanthellae are ubiquitous and critical members of coral reef ecosystems (Taylor, 1974; Muscatine and Porter, 1977; Trench, 1993; Rowan, 1998). They are normally abundant, with healthy reefs typically containing  $>10^9$  cells per  $m^2$ , but due to their small size (10  $\mu m$  diameter) their overall biomass on reefs is low. Because they are so important to the construction, evolution, and ecology of coral reefs, zooxanthellae can be regarded as keystone species on coral reefs – perhaps the only protists to play such a role.

Zooxanthellae provide significant nutritional benefits to their hosts in the form of translocated photosynthates, particularly glycerol and other water soluble compounds

such as glucose. In a variety of scleractinian corals, photosynthates from dinoflagellate zooxanthellae (in the genus *Symbiodinium*) have been shown to account for 50–95% of the coral’s energy budgets. In addition, the presence of algal symbionts drives rapid calcification in the host organism, and allows scleractinian corals to accrete limestone skeletons, dominate as the principal builders of contemporary reefs, and compete for space in the shallow tropical seas where they are most commonly found.

Recently, coral–algal symbioses have become a major focus of research inquiry as a result of coral reef “bleaching,” in which reef corals and other zooxanthellate hosts lose their algal symbionts (or experience a reduction in their per-cell pigment concentrations) and become pale or white as the calcium carbonate skeleton becomes increasingly visible through the translucent coral tissue. In some cases, residual coral pigments result in bleached corals appearing pale blue, pink, yellow, purple, chartreuse or other colors, rather than the typical white appearance.

Bleaching events are becoming increasingly frequent as a result of rising sea surface temperatures, and have been responsible for widespread coral mortality in some reef regions (Hoegh-Guldberg et al., 2007). Moreover, with ocean acidification resulting in declining rates of coral calcification, the role of algal symbionts in influencing the response of their calcifying hosts appears poised to be a similarly active research field.

### Diversity and distribution of zooxanthellae

In 1883, Karl Brandt first recognized that the “animal chlorophylls” he studied in radiolarians were, in fact, mutualistic algae (Figure 1). He introduced a new genus *Zooxanthella* to refer to these algae, but this name was quickly dropped, as the phylogenetic diversity of these algae (see Definition) became apparent.

**Zooxanthellae, Figure 1** Original drawings of “zooxanthellae” reproduced from Brandt (1883). Shown are the *Gelbe Zellen* (“yellow cells”) isolated from the scleractinian coral *Cladocora caespitosa* (“21”) and the upside-down jellyfish *Cassiopeia borbonica* (“24”). Both are *Symbiodinium* based on their appearance and host origin.

The first dinoflagellate zooxanthellae were cultured in the 1950s, and in 1962 Hugo Freudenthal introduced a new genus and species *Symbiodinium microadriaticum*, from the Greek words *symbion* (“living together”) and *dinos* (“whirling”), to describe the gymnodinioid dinoflagellates isolated from the upside-down jellyfish *Cassiopeia xamachana* (Freudenthal, 1962). Because no further species in the genus were formally described for several decades (with eight species names eventually validated by formal description in 2000), it was generally assumed that all symbiotic dinoflagellates belonged to a single pandemic species *S. microadriaticum*, despite the fact that evidence pointing to significant diversity within the genus had begun to accumulate since the 1970s.

In fact, there are currently eight genera in four or five orders of dinoflagellate that are recognized as endosymbiotic zooxanthellae in marine invertebrates and protists (Banaszak et al., 1993; Trench, 1997). *Symbiodinium* is the most studied genus in this paraphyletic group and is commonly found in shallow water tropical and subtropical cnidarians. Cnidarian species reported to contain *Symbiodinium* include many representatives from the class Anthozoa (including anemones, scleractinian corals, black corals, zoanthids, corallimorphs, blue corals, alcyonacean corals, and sea fans) and several representatives from the classes Scyphozoa (including rhizostome and coronate jellyfish) and Hydrozoa (including milleporine fire corals). *Symbiodinium* has also been identified from gastropod and bivalve mollusks (including tridacnid [giant] clams, heart cockles, and conch), large miliolid foraminifera (in the subfamily Soritinae), sponges, and a giant heterotrich ciliate (see Trench, 1993; Baker, 2003 for review). Some records of “zooxanthellae” present in invertebrates and other hosts have been based on observations of just a handful of individuals, or are based on only cursory observations or anecdotal reports. Because systematic surveys of potential hosts have not been undertaken, it is likely that additional

zooxanthellate hosts exist in nature which have yet to be reported.

Although zooxanthellae can be found in a wide variety of hosts, algal symbiosis tends not to be the norm for any particular taxonomic group. For example, while scleractinian corals are the principal builders of contemporary coral reefs, the majority of species in the order Scleractinia are in fact deep water and azooxanthellate. Moreover, some individual species are facultatively zooxanthellate, able to survive indefinitely in both a symbiotic and non-symbiotic state, depending on environmental conditions (e.g., certain species in the scleractinian coral genus *Oculina*, which is zooxanthellate in shallow water, but azooxanthellate at depth). Together, these patterns indicate that symbiosis with algae has evolved independently multiple times, even within individual groups such as anthozoans.

The life cycle of *Symbiodinium* alternates between a vegetative cyst and a motile zoospore (Figure 2), with the vegetative stage being the dominant form in endosymbiosis. Relatively little is known of the diversity and ecology of free-living *Symbiodinium*, although they are now routinely identified in reef waters and/or sediments (Carlos et al., 1999; Gou et al., 2003; Lewis and Coffroth, 2004; Coffroth et al., 2006; Littman et al., 2008; Manning and Gates, 2008; Porto et al., 2008). It is not yet clear how much *Symbiodinium* diversity exists in these free-living pools, and what overlap and/or interactions exist between these algae and those in endosymbiosis. This is currently an active area of research.

### Diversity and flexibility in coral–algal symbiosis

The dinoflagellate genus *Symbiodinium* is extraordinarily diverse, and consists of at least eight major clades (A–H, Santos and Coffroth and Santos, 2005; Pochon et al., 2006). Members of five of these clades (A, B, C, D, and F) have to date been documented in scleractinian corals. It is clear that additional diversity in *Symbiodinium* remains to be discovered, and that most species are uncultured and undescribed (Rowan, 1998; Santos et al., 2001). Moreover, in addition to the dominant populations of symbiotic dinoflagellates in these hosts, many unusual or novel variants may also occur as cryptic and unstable transients whose physiological or ecological importance is not yet clear (LaJeunesse, 2001; Santos et al., 2001; Toller et al., 2001). It is likely that additional diversity (at both the clade level and the subclade level) will be discovered with increased sampling of understudied zooxanthellate hosts, such as forams, anemones, sponges, and octocorals.

Scleractinian corals often show flexibility in the types of *Symbiodinium* they can host, both within and among clades (Baker, 2003). Although one symbiont type is usually dominant in any given coral species and environment (Rowan and Powers, 1991; LaJeunesse, 2002; LaJeunesse et al., 2003), the ability of some corals to host different symbionts in different environments or locations suggests

**Zooxanthellae, Figure 2** Life cycle of *Symbiodinium* (a) vegetative cyst, (b) dividing vegetative cyst producing two daughter cells, (c) dividing vegetative cyst producing three daughter cells, (d) developing zoospore, and (e) zoospore. CH: chloroplast; N: nucleus; AP: accumulation product; LF: longitudinal flagella; TF: transverse flagella. (Adapted from Schoenberg and Trench [1980] and Freudenthal [1962], and reproduced with permission from Stat et al. [2006].)

that these corals may possess different physiological optima depending on the algal symbiont(s) they host. Moreover, because these corals appear able to change the dominant symbiont type in response to environmental changes (Rowan et al., 1997; Rowan, 1998; Baker, 2001, 2003; Little et al., 2004; Berkelmans and Van Oppen, 2006; Jones et al., 2008; LaJeunesse et al., 2009), it has been suggested that flexibility in coral–algal symbiosis is an important mechanism by which reef corals adapt or acclimatize to disturbances, including those resulting from climate change (Buddemeier and Fautin, 1993; Baker, 2001, 2003; Baker et al., 2004; Berkelmans and Van Oppen, 2006). Although evidence exists in support of these hypotheses, the large-scale implications for coral reef survival through the coming century have yet to be established (Hoegh-Guldberg et al., 2007). In addition, there are likely to be trade-offs between different symbiont types (Little et al., 2004) that have yet to be explored in detail. Diversity and flexibility in coral–algal symbiosis remain an active area of research for exactly these reasons.

## Summary

The endosymbiosis between scleractinian (stony) corals and zooxanthellae (typically symbiotic dinoflagellates in the genus *Symbiodinium*) underpins the success of modern

coral reefs. Reef corals (and other contemporary reef-builders) gain a twofold advantage by hosting zooxanthellae. First, they can function as autotrophs and use the photosynthates thus obtained as an energy substrate. Second, for reasons which remain unclear, they are able to calcify much faster than their azooxanthellate counterparts (Cohen and McConnaughey, 2003). Together these phenomena explain why coral reefs have become dominant ecosystems in shallow, oligotrophic tropical seas. They also explain why coral reef bleaching (the loss of zooxanthellae from reef-builders) as a result of environmental stress is a major threat to coral reef ecosystems, particularly as a result of climate change-related seawater warming. The potential role of zooxanthellae in mediating the response of reef builders to ocean acidification also illustrates their importance as a contemporary subject of research.
